1.0 Introduction

Lodgepole pine (*Pinus contorta* var. *latifolia* Engelm.) is Alberta's provincial tree. It is the most common tree species in the Rocky Mountains and foothill regions, occurring on the eastern slopes of the the Rocky Mountains, as well as in a large zone to the east in boreal regions where it hybirdizes with jack pine (*Pinus banksiana* Lamb.). During the early years of European settlement, lodgepole pine was used by pioneers primarily for fence-posts, fuelwood and cabin construction. Long before that, the Western Plains Indians used these strong, straight, and uniformly tapered trees for the construction of buffalo-skin lodges that led the famous explorers Lewis and Clark to dub them "lodgepole pine".

Today, lodgepole pine continues to be a major contributor to Alberta's forest industry as well as providing protective cover for the vital watersheds of the province's eastern slopes. Although it comprises only about 20 percent of the mature standing timber in Alberta, it accounts for approximately 40 percent of the annual harvest in the province. Lodgepole pine is mostly used for lumber and plywood as well as pulp. The lumber is used primarily in general constructions. Other uses include furniture, flooring, panels, and siding. After pressure treatment with preservatives, lodgepole pine makes excellent mine timbers, railway ties, landscaping and fencing materials, and utility poles.

Lodgepole pine grows well on a wide array of sites. It has a growth optima on similar sites to those of aspen (*Populus tremuloides* Michx.) and white spruce (*Picea glauca* (Moench) Voss); moist, rich, well-aerated sites with friable soils and long, warm growing seasons. Better sites in the Lower Foothills natural subregion of Alberta have these conditions, and succession after wildfire in this subregion is unpredictable and may favour either aspen or lodgepole pine depending on site conditions, history, and chance. Unlike aspen and white spruce, however, lodgepole pine can tolerate sites that have short and irregular growing seasons, poor to very poor nutrient regimes, and a distinct moisture deficit. The Upper Foothills subregion and the Subalpine subregion of Alberta's eastern slopes have extensive areas with these site conditions, although moisture deficits in these high precipitation areas are largely restricted to sites of coarser texture and during periods of unusually low precipitation.

Over the last several decades, both the government and the industry in Alberta have allocated a sizeable amount of time and resources to the development of yield tables for lodgepole pine stands. Forest practitioners and researchers in Alberta have made great strides and gained considerable knowledge on the biology and the growth and yield of lodgepole pine stands. Large amounts of data have been collected and new experiments are being designed and carried out throughout the range of lodgepole pine. While some general trends and consensus have emerged from numerous trials and experiments completed so far, a more accurate quantification and a satisfactory modelling of the growth and yield of lodgepole pine stands under an array of assorted site quality and stand density conditions, has yet to be achieved. Many studies on lodgepole pine focus on case-specific situations with very limited generality.

As Alberta moves strategically and progressively towards the implementation of enhanced forest management (EFM) based on sound and practical ecological principles, more accurate information about the growth and yield of lodgepole pine stands is urgently required to guide practitioners, decision-makers, and planners on the most likely responses of these stands under alternative silvicultural and management strategies. This is particularly true for stands regenerated following harvesting. In addition to providing the essential growth and yield information from which a long-term sustainable annual allowable cut (AAC) can be determined, such information can also be used to assess alternative silvicultural practices such that the most advantageous option can be identified based on pre-specified constraints relating to costs, revenues, utilization standards, rotation ages, product quality, etc.

The increased values and pressures on the timber resources in Alberta, resulting from alternative land uses, landbase withdrawals, mill expansions and the like, means that growth and yield estimates must be accurate enough in the prediction of stand and forest level responses to varying site quality and stand density conditions and management strategies. To choose the best management strategy, it is necessary to have a quantitative means for judging contrasting strategies that emphasizing different tree and stand characteristics, and different management objectives.

As an integral component of a project entitled "GYPSY – A Growth and Yield Projection System for Seed-origin, Planted and Treated Lodgepole Pine Stands Within An Ecologically Based Enhanced Forest

Management (EFM) Framework", a version of GYPSY for seed-origin natural and regenerated lodgepole pine stands was developed. The main objective of this version was to assess and quantify the growth and yield of seed-origin natural and regenerated lodgepole pine stands in relation to site quality, stand density and stand age. This was accomplished by incorporating the potential variables that represent the site and stand density effects into the models that make up the growth and yield projection system. The provincial permanent sample plot (PSP) data base for lodgepole pine was used for developing the base models. This PSP program was initiated in 1960, with the prime objective of developing fully-stocked normal yield tables for stands free of major disturbance. A more detailed description of the PSP system is provided in Alberta Land and Forest Service (2000).

GYPSY can be considered as an integrated model that predicts the development of both natural and regenerated (post-harvest) lodgepole pine stands. One of the notable characteristics of GYPSY is its ability to generate compatible predictions on three levels of detail: whole stand, diameter class/distribution, and individual tree. While intrinsically GYPSY may still be considered as a diameter distribution model in the commonly accepted classification system of three model categories (whole stand, diameter distribution and individual tree), it in fact encompasses many characteristics associated with whole stand models and individual tree models, and can be used as a whole stand model, a diameter class/distribution model and a distance-independent individual tree model. GYPSY can produce individual tree estimates without having the need of developing individual tree models. The predictions generated from GYPSY are guaranteed to be compatible, regardless of the type of model it is assumed to be. This eliminates the need to construct some potentially fairly subjective procedures for reconciling the incompatible predictions that typically arise when different types of model are used.

Definitions for several key variables that are used throughout the text are provided below. These variables represent important conceptual and practical components of the GYPSY model.

Stand density and average diameter – stand density (N) refers to the number of stems per hectare (stems/ha) for trees taller than 1.3 m. Because of the complexities associated with very small trees and the inconsistencies in measuring these trees over the last four decades, GYPSY was developed excluding any tree that is shorter than 1.3 m without a diameter (unless otherwise defined, the word "*diameter*" indicates DBH - diameter outside bark at a breast height of 1.3 m above ground). Average diameter (D) is defined as the arithmetic mean diameter for all trees taller than 1.3 m in the stand.

Because the above definitions for stand density and average diameter are based on the same set of trees (all taller than 1.3 m), they can be considered compatible. If stand density was defined as the total number of stems per ha for all trees in the stand including those shorter than 1.3 m, a compatible measure that corresponds to stand density would be average root collar diameter. It can be problematic sometimes when average diameter is obtained from trees taller than 1.3 m and stand density is obtained from all trees including those shorter than 1.3 m.

Stand density factor – Stand density factor is a new stand density measure developed in GYPSY. It is defined as the stand density at a reference breast height age of 50 years.

Stand density factor (SDF) plays a pivotal role in stand density projections. It resembles the site index (SI) concept. SDF in a mortality model acts like SI in height and site index models.

Top height – Top height (H_{TOP}) is defined as the average height of the 100 largest diameter trees per ha. While this top height definition may appear simple and straightforward, it in fact is one of the most intriguing and ambivalent terms that one will probably ever encounter in growth and yield studies. There are other definitions of top height. The lack of a precise definition for top height is caused by the fact that the size of a sample plot is seldom as large as 1-ha, and the top height trees selected in plots less than 1-ha may not accurately represent the actual, per ha based top height trees. Magnussen (1999) evaluated the biases of top height estimates from different plot sizes. Various remedies were proposed to reduce the biases under different assumptions and constraints (Rennolls 1978; Iles et al. 1990; Soderberg and Nigh 1994; García 1998).

Since the selection of top height trees (largest DBH trees) is objective, consistent and repeatable, the use of top height is recommended. An evaluation of the biases of top height estimates from different

plot sizes suggested that for lodgepole pine stands in Alberta, the biases are negligible, so long as the plot size is equal to or greater than 0.03 ha (Huang et al. 2001a). Thus, in practice, it is recommended that top height be obtained by averaging the heights of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot.

Site index – site index is defined as the top height at 50 years breast height age. Site index can also be defined as the top height at 50 years total age. In GYPSY, both definitions of site index are used. Unless a more specific term such as "total age based site index" is used, site index always refers to the top height at 50 years breast height age.

The site index curves developed in GYPSY for seed-origin natural and regenerated lodgepole pine were constructed from repeatedly measured permanent sample plots covering a wide range of sites. Site index curves constructed from PSPs generally produce more realistic stand level height estimates and are often considered more ideal than those constructed from stem analysis data (Curtis 1964; Huang 1997).

Stand height – stand height (H_{DC}) is defined as the average height of dominant and co-dominant trees in the stand. It is one of the stand level variables frequently used to describe site quality. In practice, stand height is usually obtained by averaging the heights of one dominant tree and two co-dominant trees selected in an area of 0.01-ha or larger.

The dominant and co-dominant trees associated with stand height are widely used as site trees. An advantage of using these trees as site trees is that the average height of dominant and co-dominant trees can be interpreted easily from medium or large-scale aerial photography. However, the definition of "dominant" and "co-dominant" is somewhat subjective, and different people may have different opinions on which tree is dominant and which tree is co-dominant. This can result in considerable discrepancies in the selection of site trees, causing inconsistent and unrepeatable site index estimates. Nicholas et al. (1991) examined the variation in the classification of tree crown positions and found that "the overall similarity of reclassification was only 72.1%", and "human classification errors may contribute to variation in site index estimates". For these reasons, GYPSY focuses on the use of top height as the site index measure.

The most important reason that GYPSY focuses on top height rather than stand height is that the selection of top height trees (largest DBH trees) per unit area is objective, consistent and repeatable. The repeatability is desirable in applications because it removes the subjectiveness associated with "dominant" and "co-dominant" trees. However, because stand height (dominant and co-dominant height) is still widely used in Alberta, especially in photo-based forest inventories, both top height and stand height are used in GYPSY. Users can choose either one or both of them depending on the specific circumstance involved. A relationship between stand height and top height was developed (see Section 3.4). It can be used to make conversions between stand height and top height.

There are three base models in GYPSY: the top height-site index model, the mortality model, and the Weibull diameter distribution function. The three base models constitute the foundation from which all GYPSY projections are made. The top height–site index model describes the growth of top height. It also functions as a site index prediction model, and can be used to make site-specific conversions among the three types of age (breast height age, stump age and total age). The mortality model describes the stand density dynamics. It provides site-specific stand density estimates at any point in time, including those at breast height age 50 (stand density factor) and breast height age zero (initial density).

The Weibull diameter distribution function describes the diameter distribution of a given stand with known values of site index, stand density and age. It was estimated using a one-step parameter prediction approach, on the combined cumulative distribution data from all sample plots. The conventional two-step parameter recovery procedure of fitting separate Weibull distribution to the diameter-class frequency data from each individual plot, and then regressing the estimated parameters to other plot-level variables such as site index, stand density and stand age (Clutter et al. 1983), was found to be less efficient than the one-step parameter prediction approach.

In GYPSY, the Weibull diameter distribution function was partitioned into an individual tree model. The partitioning process involves the use of the "inverse-distribution" technique (Huang 2001), a concept

derived from the inverse-regression approach (Draper and Smith 1998). Essentially, GYPSY partitions the estimated Weibull diameter distribution function into various narrow diameter classes of unequal intervals, such that there is only one tree appearing in each class. Integration of the partitioned classes at different levels of resolution produces compatible growth and yield estimations at whole stand, diameter class, and individual tree levels.

There are many factors that can influence the growth and yield of natural and regenerated stands. For pure lodgepole pine stands, the most common and important factors are site quality, stand density and age (most of the other factors are directly or indirectly related to these three factors). Site quality describes the carrying capacity of the environment. It is determined by the bio-geo-climatic conditions of a site. Stand density describes the degree of occupancy (or crowding) of a site. It is determined by both the number and the size of trees growing on the site. Because the models developed in GYPSY included site quality, stand density and age as independent variables, and because there is no irrefutable evidence to suggest that the site quality and stand density relationships between seed-origin natural and seed-origin regenerated pine stands are intrinsically different, so long as the values of site quality, stand density and age are known and the models behave appropriately within a wide range of site and stand density conditions, growth and yield projections can be made. This explains why GYPSY is applicable to both seed-origin natural and seed-origin regenerated lodgepole pine stands.

It is not well understood at this time how accurate the absolute prediction of yield made by GYPSY may be on the forest level. Since the models were developed and calibrated primarily with data from PSPs located in stands free from major disturbance, it is possible that the average forest level responses are not adequately represented by the models. In stands free from irregular mortality caused by forest fire, insect and disease, and severe weather such as wind, drought and ice storms, GYPSY should, however, provide relatively accurate predictions. If observations of irregular mortality are available, adjustments of the yield estimation can be made following the procedures described in Huang (2001).

A SAS based computer program is written to assist the computations associated with this version of GYPSY. The program is mainly designed to provide growth and yield estimation for seed-origin natural and regenerated lodgepole pine stands under various site, density and age consitions. It can also be used to show the estimated results in graphical and tabular forms. In order to run this program, either one of two sets of input variables can be used:

(I). Initial density and site index;
(II). Current observed density, top height and age (breast height age, stump age, or total age).

The yield relationships shown in Appendix 1 were generated from this program, based on the first set of input variables. Because the second set of input variables can be readily converted into the first set of input variables through the top height–site index model and the mortality model, the yield relationships shown in Appendix 1 can also be used when the second set of input variables are obtained from existing stands. If an exact match between the site and density values shown in Appendix 1 and their counterparts obtained from an existing stand is not available, approximations of the growth and yield projections can be made through linear interpolation.

In addition to the SAS based computer program, a yield table generator called ExcelGYPSY was developed to facilitate the application of GYPSY. ExcelGYPSY works in a Microsoft Excel environment. It is based on the Microsoft visual basic programming system, and is not restricted to the Microsoft Windows operating system. A user's guide for ExcelGYPSY is planned to be released at a later date. For the time being, ExcelGYPSY is available only to authorized individuals and organizations. It is expected that once the other GYPSY modules are completed, ExcelGYPSY will be made more widely available.

The primary objective of this report is to present the yield relationships in tabular form, such that users can access and evaluate the growth and yield of seed-origin natural and regenerated lodgepole pine stands promptly without the need of going into the details. A number of the models used to generate the yield relationships shown in Appendix 1 are presented here. Other models and the fundamentals that form the basis of GYPSY, together with some of the more technical aspects related to GYPSY, are described in Huang (2001).

2.0 The Base Models

The base models used to generate the yield curves shown in Appendix 1 include the top height–site index model, the mortality model, and the Weibull diameter distribution function.

2.1 The Top Height–Site Index Model and Site Index Prediction Tables

Two congruent versions of the top height-site index model were used in GYPSY. One is based on total age (totage), and the other is based on breast height age (bhage). The two versions are described by the same functional form. They provide compatible and mutually interchangeable top height and site index estimates from totage or bhage.

The top height-site index model based on total age

Evaluation of alternative height-site index models suggested that the following model, derived from the difference equation approach (Huang 1997), was appropriate for lodgepole pine in Alberta:

$$[1] \quad H_{TOP} = SI_{totage} \times \left(\frac{1 + \exp(b_1 + b_2\sqrt{\ln(1+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})}{1 + \exp(b_1 + b_2\sqrt{\ln(1+totage)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})} \right)$$

where: H_{TOP} = top height (m), which is defined as the average height of the 100 largest DBH trees per ha; SI_{totage} = total age based site index (m), which is defined as the top height at 50 years total age; totage = total age of the stand (years); exp = exponent; ln = natural logarithm; b_1 = 10.967495; b_2 = -5.417569; b_3 = -0.167170; and b_4 = 0.158292. Figure 1 shows the site index curves generated from [1].

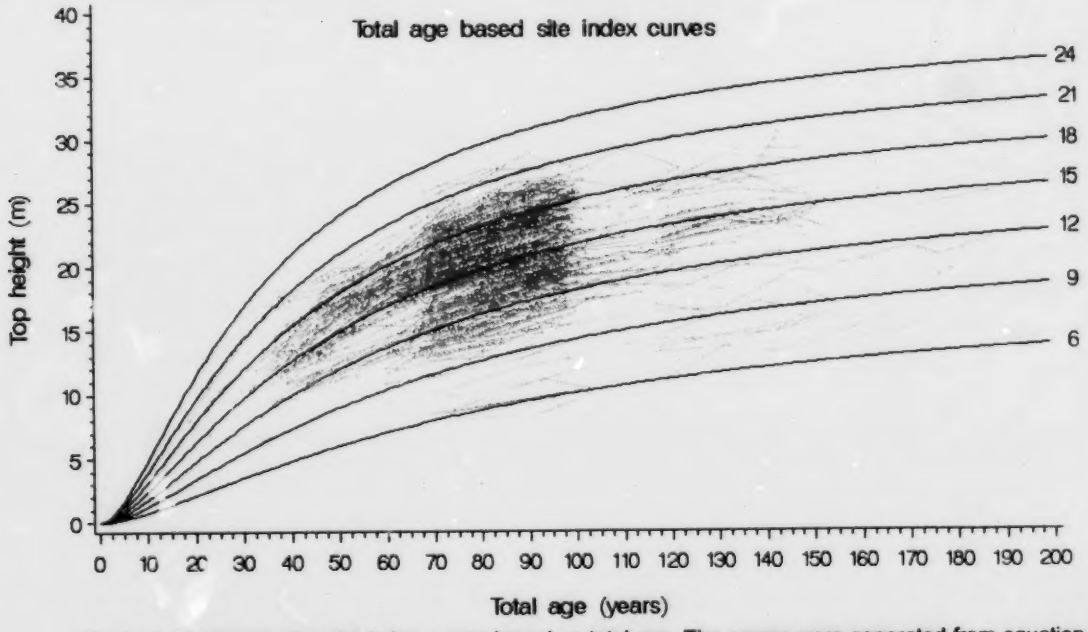

Figure 1. Lodgepole pine site index curves based on total age. The curves were generated from equation [1] using site index (SI_{totage}) values of 6, 9, 12, 15, 18, 21 and 24 m. Site index in this graph refers to top height at 50 years total age. The observed top height–total age trajectories from PSPs are also shown in this graph.

The top height-site index model based on breast height age

Total age based site index SI_{totage} was used in equation [1]. Traditionally, breast height age based site index (SI_{bhage} or simply SI), defined as the top height at 50 years bhage, is more commonly used in

Alberta and some other jurisdictions. In order to see how [1] can be re-written as a bhage based site index model, [1] is expressed as [2] for the specific height-age pair of H_{TOP} = 1.3 (m) and totage = Y2BH (years), where Y2BH is the years needed to reach the breast height of 1.3 m above ground:

$$[2] \quad 1.3 = SI_{totage} \times \left(\frac{1 + \exp(b_1 + b_2\sqrt{\ln(1+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})}{1 + \exp(b_1 + b_2\sqrt{\ln(1+Y2BH)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})} \right)$$

Since totage = (Y2BH + bhage), when bhage = 50, totage = (Y2BH + 50) and $H_{TOP} = SI_{bhage}$. Substituting the height-age pair of $H_{TOP} = SI_{bhage}$ and totage = (Y2BH + 50) into [1] produces:

$$[3] \quad SI_{bhage} = SI_{totage} \times \left(\frac{1 + \exp(b_1 + b_2\sqrt{\ln(1+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})}{1 + \exp(b_1 + b_2\sqrt{\ln(1+Y2BH+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})} \right)$$

Based on the two-equation system of [2]–[3], if SI_{totage} is available, the two unknown variables SI_{bhage} and Y2BH can be solved numerically; if SI_{bhage} is available, the two unknown variables SI_{totage} and Y2BH can be solved numerically. Therefore, given the SI_{bhage} values, equation [1] can be used to generate bhage based site index curves, which are shown in Figure 2.

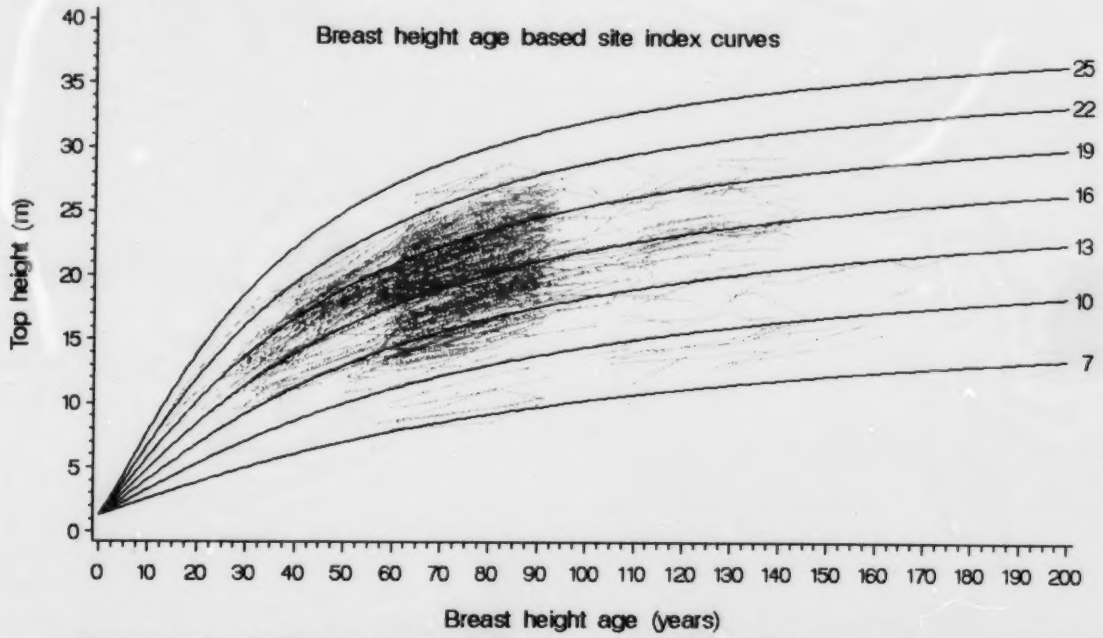

Figure 2. Lodgepole pine site index curves based on breast height age. The curves were generated from [1], based on the two-equation system of [2]-[3] and site index (SI_{bhage}) values of 7, 10, 13, 16, 19, 22 and 25 m. Site index in this graph refers to top height at 50 years bhage. The observed top height–bhage trajectories from PSPs are also shown in this graph. Each trajectory represents repeated measurements for one PSP.

Because SI_{bhage} is more commonly used in Alberta, unless a more specific term such as "total age based site index" is used, subsequent graphs and tables are all generated based on SI_{bhage}. For simplicity, SI_{bhage} is frequently referred to as SI.

Lodgepole pine height growth and site index prediction tables

Three site index prediction tables are shown here. They are based on totage (Table 1), stump age (Table 2) and bhage (Table 3). All three tables predict the bhage based site index (SI) from observed top height and one of the three ages. In practice, top height and age can be obtained by averaging the heights and ages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot.

Table 1. Lodgepole pine site index prediction table based on top height and **total age**.

Total age (years)	Site index (SI, m) at 50 years bhage

Site class	SI ranges (m)	Average SI value (m)	Definition	Timber productivity rating (TPR)
1	0 < SI ≤ 7	6	Unproductive	U
2	7 < SI ≤ 12	10	Fair/poor	F
3	12< SI ≤ 16	14	Medium	M
4	16 < SI ≤ 20	18	Good	G
5	SI > 20	22	Superior	S

Note: top height is the average height of the 100 largest DBH trees per ha, SI is site index, defined as the top height at 50 years breast height age (bhage), totage is the total age of the stand (years), and Y2BH is the years needed to reach the breast height of 1.3 m above ground. In practice, top height and totage can be obtained by averaging the heights and ages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot

Table 2. Lodgepole pine site index prediction table based on top height and **stump age**.

Stump age (years)	Site index (SI, m) at 50 years bhage

Site class	SI ranges (m)	Average SI value (m)	Definition	Timber productivity rating (TPR)
1	0 < SI ≤ 7	6	Unproductive	U
2	7 < SI ≤ 12	10	Fair/poor	F
3	12< SI ≤ 16	14	Medium	M
4	16 < SI ≤ 20	18	Good	G
5	SI > 20	22	Superior	S

Note: top height is the average height of the 100 largest DBH trees per ha, SI is site index, defined as the top height at 50 years bhage, stump age is the age measured at the stump height of 0.3 m above ground, and Y2BH is the years needed to reach breast height (1.3 m). In practice, top height and stump age can be obtained by averaging the heights and ages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot.

Table 3. Lodgepole pine site index prediction table based on top height and **breast height age**.

Bhage	Site index (SI, m) at 50 years bhage																						
(years)	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26

3	12< SI ≤ 16	14	Medium	M
4	16 < SI ≤ 20	18	Good	G
5	SI > 20	22	Superior	S

Note: top height is the average height of the 100 largest DBH trees per ha, SI is site index, defined as the top height at 50 years breast height age (bhage), and Y2BH is the years needed to reach breast height (1.3 m). In practice, top height and bhage can be obtained by averaging the heights and bhages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot.

2.2 The Mortality Model, Stand Density Factor and Initial Density

The observed mortality trajectories from lodgepole pine PSPs are shown in Figure 3. The mortality model based on these trajectories takes the form shown in [4]. It was derived using the difference equation technique frequently seen in estimating site index models (Clutter et al. 1983; Huang 1997).

$$[4] \quad N_2 = b_0 + (N_1 - b_0) \times \left(\frac{1 + \exp[b_1 + b_2 \ln(1 + bhage_1) + b_3 \ln(SI_{totage})]}{1 + \exp[b_1 + b_2 \ln(1 + bhage_2) + b_3 \ln(SI_{totage})]} \right)$$

$$b_0 = 250.818200 \qquad b_1 = -\pi \times \left((\pi/5) / \sqrt{N_1/1000} + 4.051135 \right)$$

$$b_2 = 1.968526 \times (N_1/1000)^{1/bhage_1} \qquad b_3 = 2.360369$$

where $bhage_1$ and $bhage_2$ are breast height ages at time one and time two; N_1 and N_2 are stand density (in stems/ha) at $bhage_1$ and $bhage_2$, respectively; and SI_{totage} is the total age based site index, defined as the top height at 50 years total age. Using 50 years bhage as the reference age and defining the stand density at 50 years bhage as the Stand Density Factor (SDF), equation [4] can be re-written as follows:

$$[5] \quad N = b_0 + (SDF - b_0) \times \left(\frac{1 + \exp[b_1 + b_2 \ln(1 + 50) + b_3 \ln(SI_{totage})]}{1 + \exp[b_1 + b_2 \ln(1 + bhage) + b_3 \ln(SI_{totage})]} \right)$$

$$b_0 = 250.818200 \qquad b_1 = -\pi \times \left((\pi/5) / \sqrt{SDF/1000} + 4.051135 \right)$$

$$b_2 = 1.968526 \times (SDF/1000)^{1/50} \qquad b_3 = 2.360369$$

Equation [5] is a special variant of the difference equation [4], with N_1 replaced by SDF and $bhage_1$ by the reference bhage 50. Having the current stand density N, bhage and SI_{totage} (if SI_{bhage} is available, it can be converted into equivalent SI_{totage}), SDF can be solved numerically from equation [5]. Once SDF is known, stand density at any other bhage can be obtained from [5]. Figures 4 and 5 show some example mortality curves generated from equation [5].

The stand density factor (SDF) plays a pivotal role in stand density projections. In essence, SDF in a mortality model acts like SI in site index models. It provides the basis for stand density projections (just like SI provides the basis for height projections). On any given site, SDF was found to be approximately independent of age. This is quite unique among many stand density measures. The mortality model [5] is one of the most important drivers in GYPSY. It is also one of the most difficult models to develop.

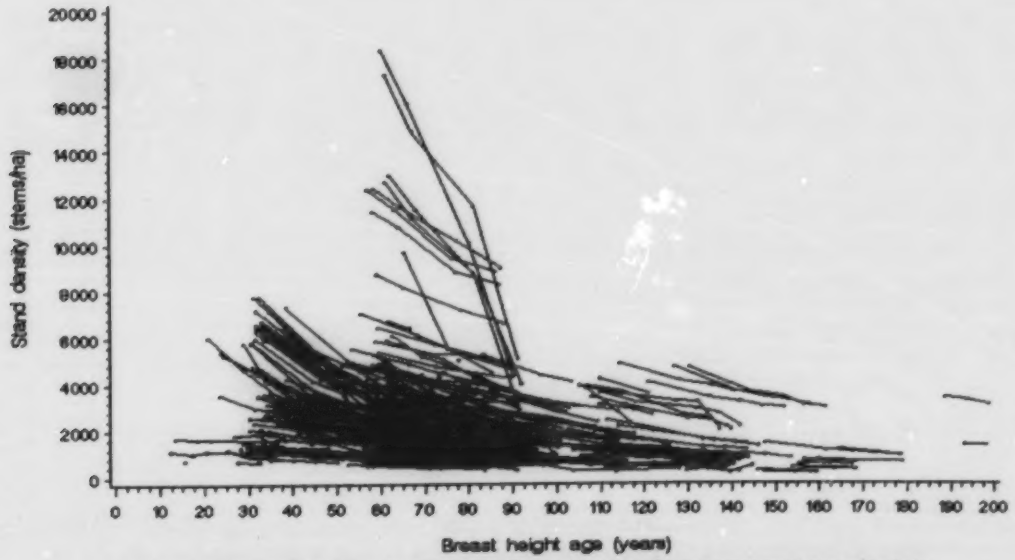

Figure 3. Observed lodgepole pine mortality trajectories from permanent sample plots.

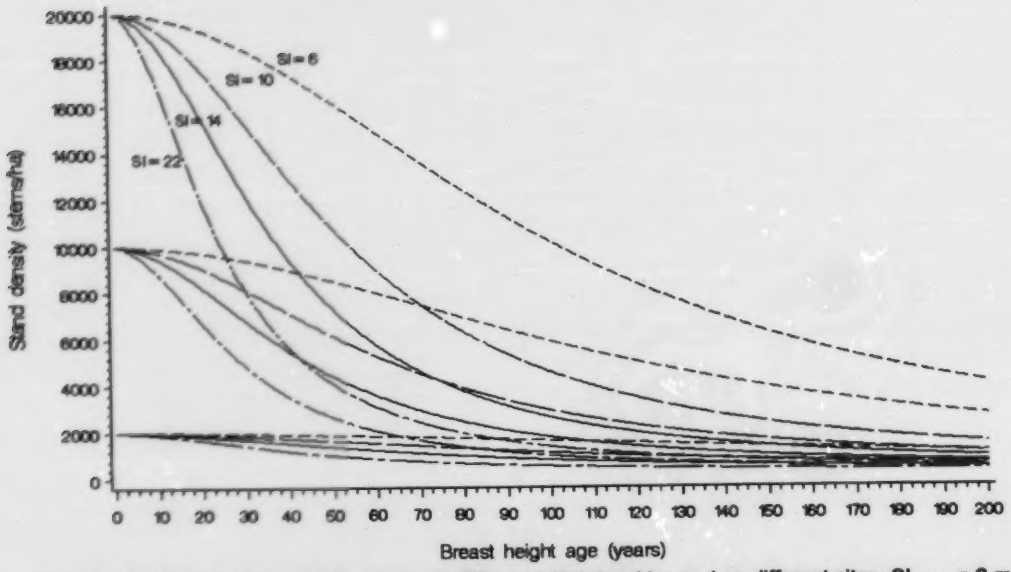

Figure 4. Lodgepole pine mortality curves at different initial densities and on different sites: SI_{bhage} = 6 m (short dash), SI_{bhage} = 10 m (long dash), SI_{bhage} = 14 m (solid), and SI_{bhage} = 22 m (dot-dash).

Estimating initial density

The mortality function [5] can be used to estimate stand density at any breast height age. One of the most important usages of this function is to derive the initial density N_0 at bhage zero. To estimate N_0 from [5], three variables must be known beforehand: current density N (stems/ha), bhage and SI_{totage} (or SI_{bhage}). If SI_{totage} (or SI_{bhage}) is unknown, top height can be used instead.

Assuming that the three variables (N, bhage, and SI_{totage}) are known, SDF can be derived numerically from [5]. Once SDF is known, initial density at bhage zero is calculated by:

$$[6] \quad N_0 = b_0 + (SDF - b_0) \times \left(\frac{1 + \exp[b_1 + b_2 \ln(1+50) + b_3 \ln(SI_{totage})]}{1 + \exp[b_1 + b_2 \ln(1+0) + b_3 \ln(SI_{totage})]} \right)$$

where b_0-b_3 are the same as in [5]. For most practical purposes, the initial density at bhage zero can also be assumed to be the initial density at totage zero. This is because the early mortality trajectories observed from the provincial stand dynamics and monitor plot data, resemble horizontal lines in almost all cases.

Sometimes, the initial stand density at bhage zero is known (or assumed to be known). In order to estimate future stand densities, SDF must be solved first from equation [6]. This can be achieved by using an iterative routine similar to that described by Huang (1994b). Once SDF is available, site-specific stand density at any bhage can be projected directly from equation [5]. As an example, assuming that the initial density at bhage = 0 is: N_0 = 7000 (stems/ha), and SI_{bhage} = 16 m (or SI_{totage} = 14.6878 m). From equation [6], SDF can be solved iteratively to give SDF = 2986. Once SDF is available, predicted stand densities at bhage 10, 30, 50, 80, 100 and 150 are found to be 6579, 4638, 2986, 1680, 1243 and 732, respectively, which are obtained by substituting the SDF and bhage values into [5].

Table 4 lists the stand density projections at different initial densities, and on different sites. It can be used to predict stand density at any age, and estimate initial density from current density. For instance, for an existing stand with an observed density of 1288 (stems/ha), if the current bhage is 125 (years) and the site index is 14 (m), the estimated stand density factor (N at bhage 50) is 4414 (Part 5, Table 4), which corresponds to an initial density of 10000. Given this initial density, the entire stand density trajectory can be read directly from Table 4. If an exact match of the density observations is not available, interpolations or approximations for the stand density projections can be made based on Table 4 and Figure 5.

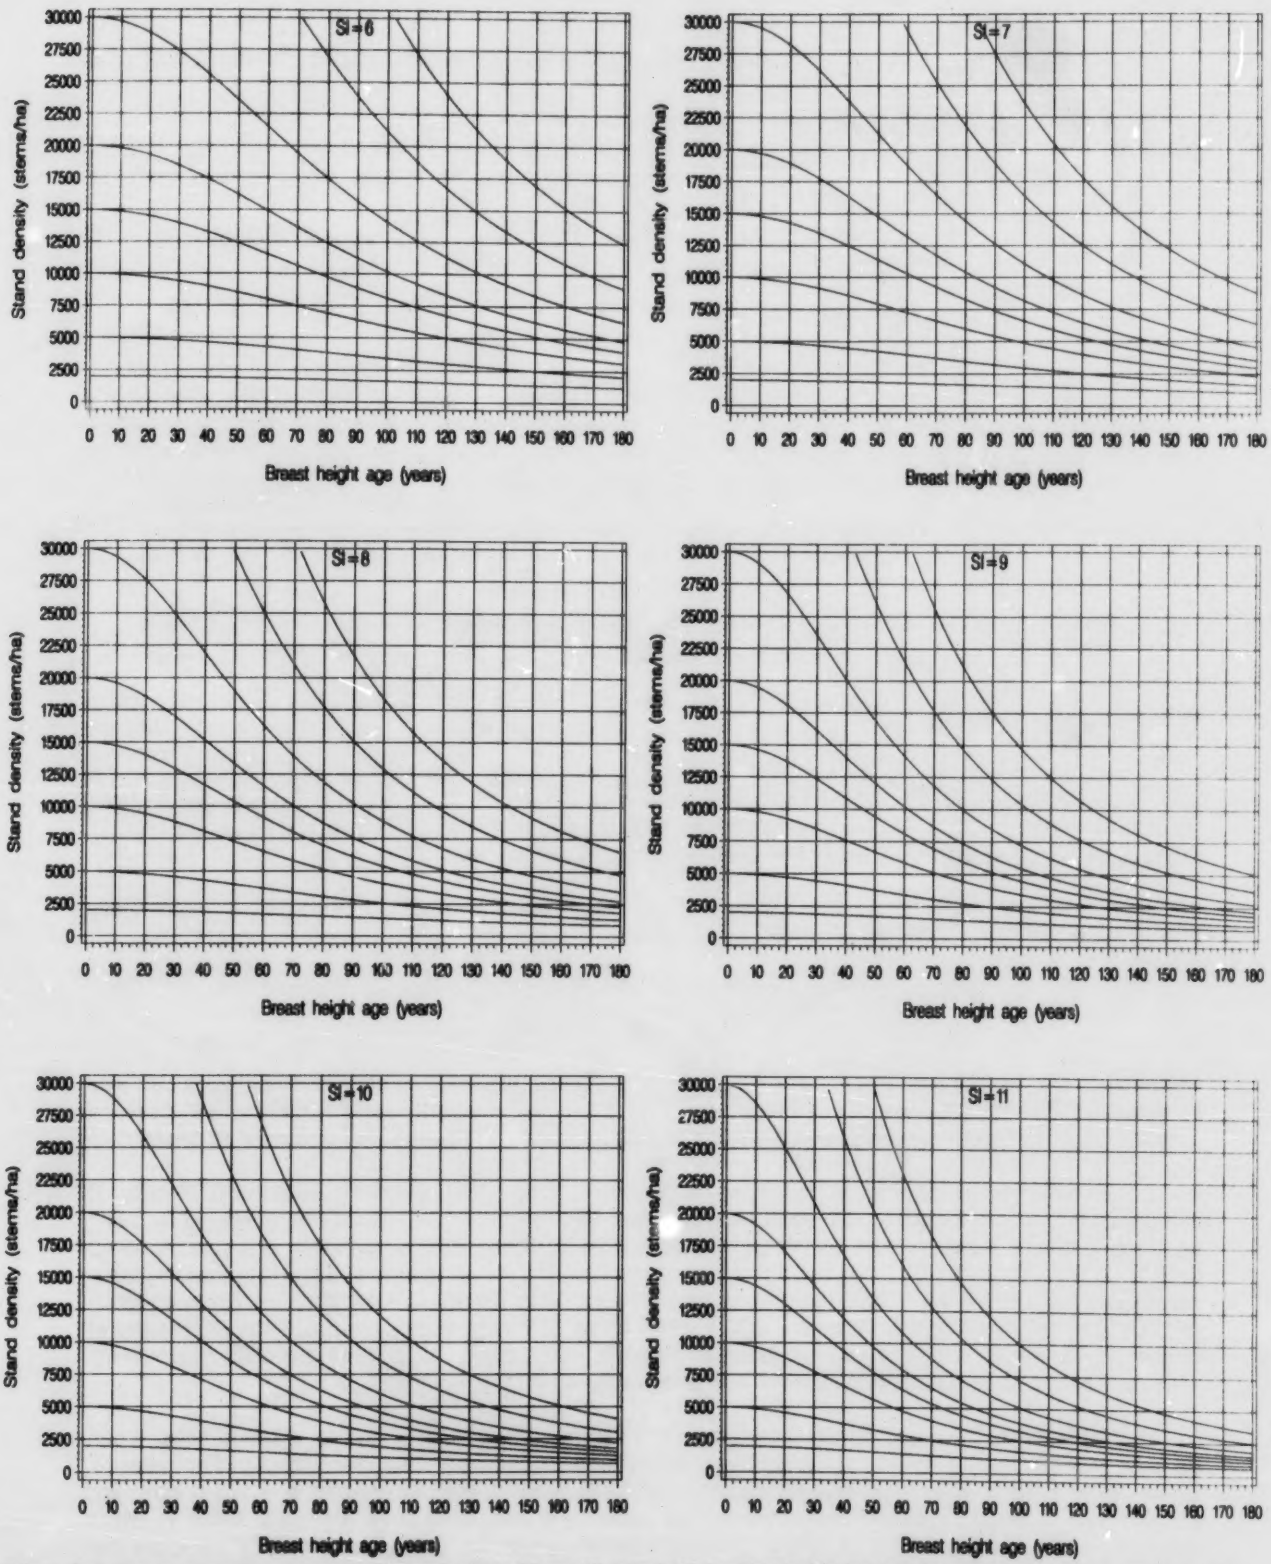

Figure 5. Example mortality curves on different sites. Where SI (site index) refers to the top height at 50 years bhage. Eight initial densities are shown in each graph: 2000, 5000, 10000, 15000, 20000, 30000, 50000 and 80000 (stems/ha).

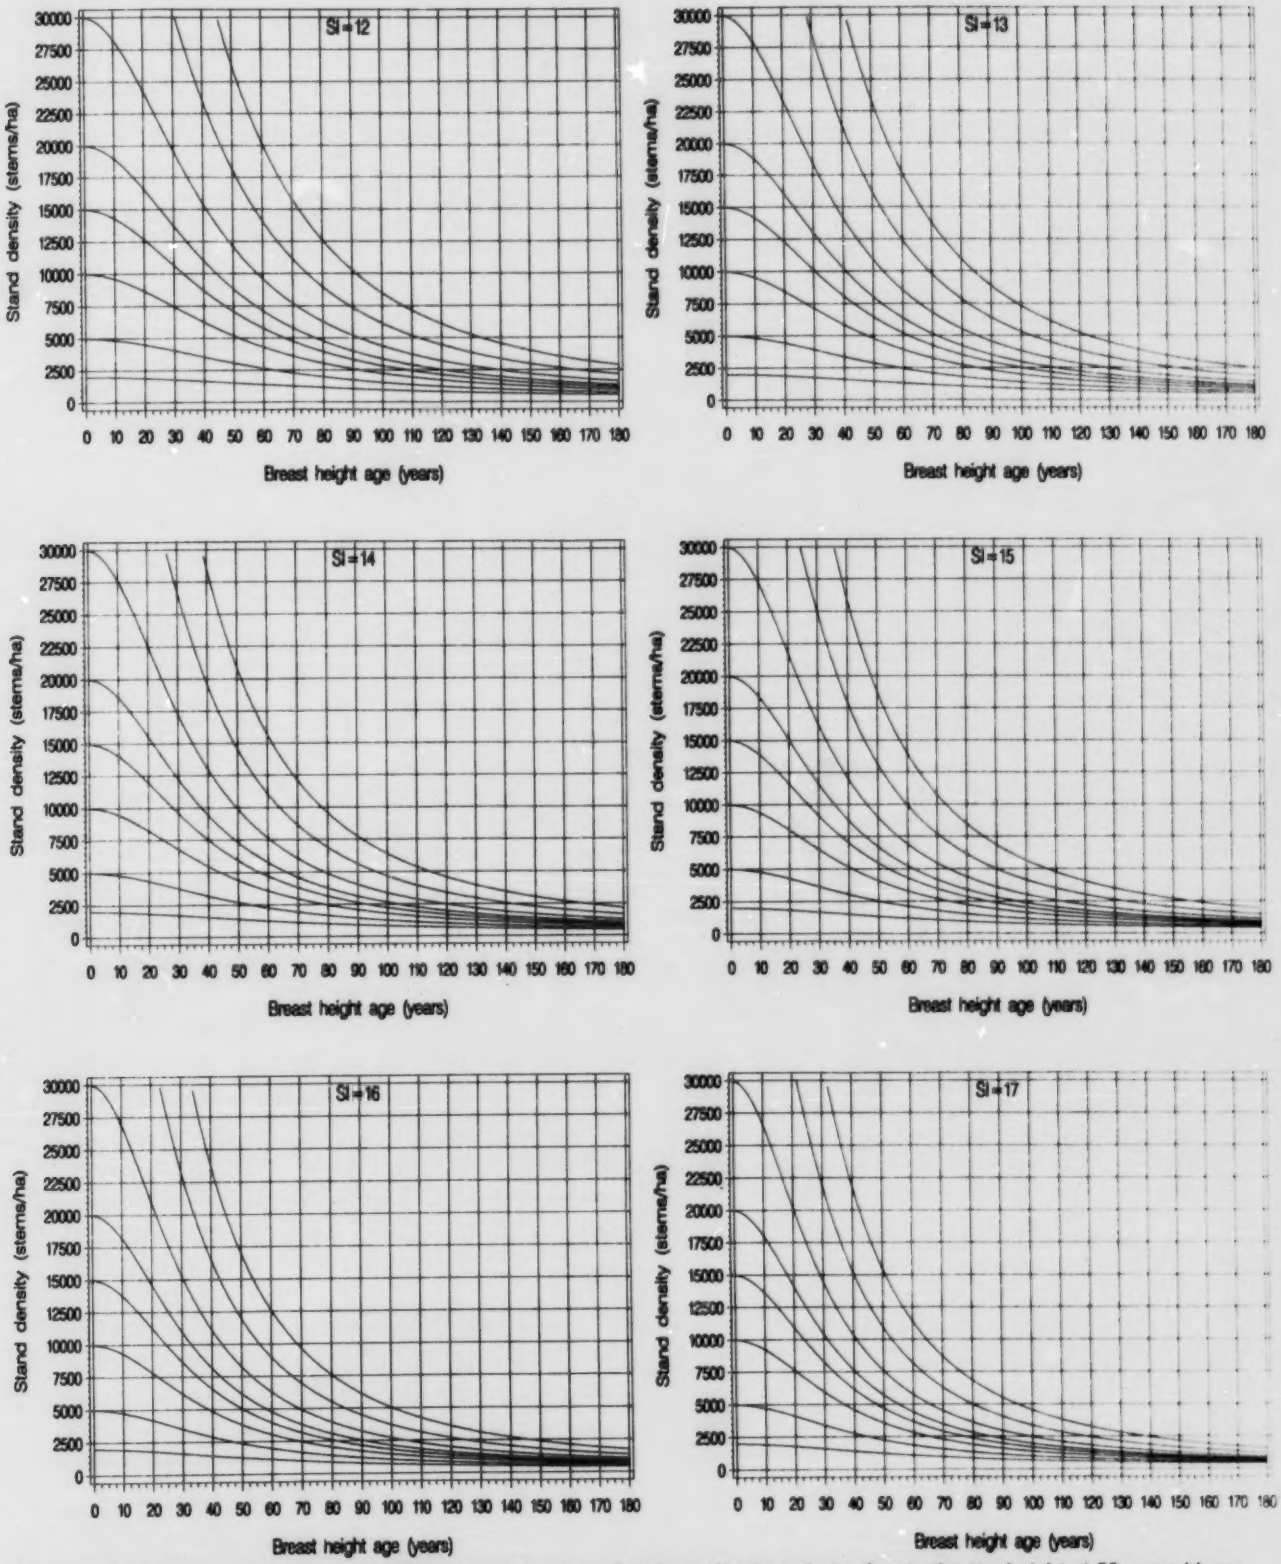

Figure 5. Example mortality curves on different sites (continued). Where SI (site index) refers to the top height at 50 years bhage Eight initial densities are shown in each graph: 2000, 5000, 10000, 15000, 20000, 30000, 50000 and 80000 (stems/ha).

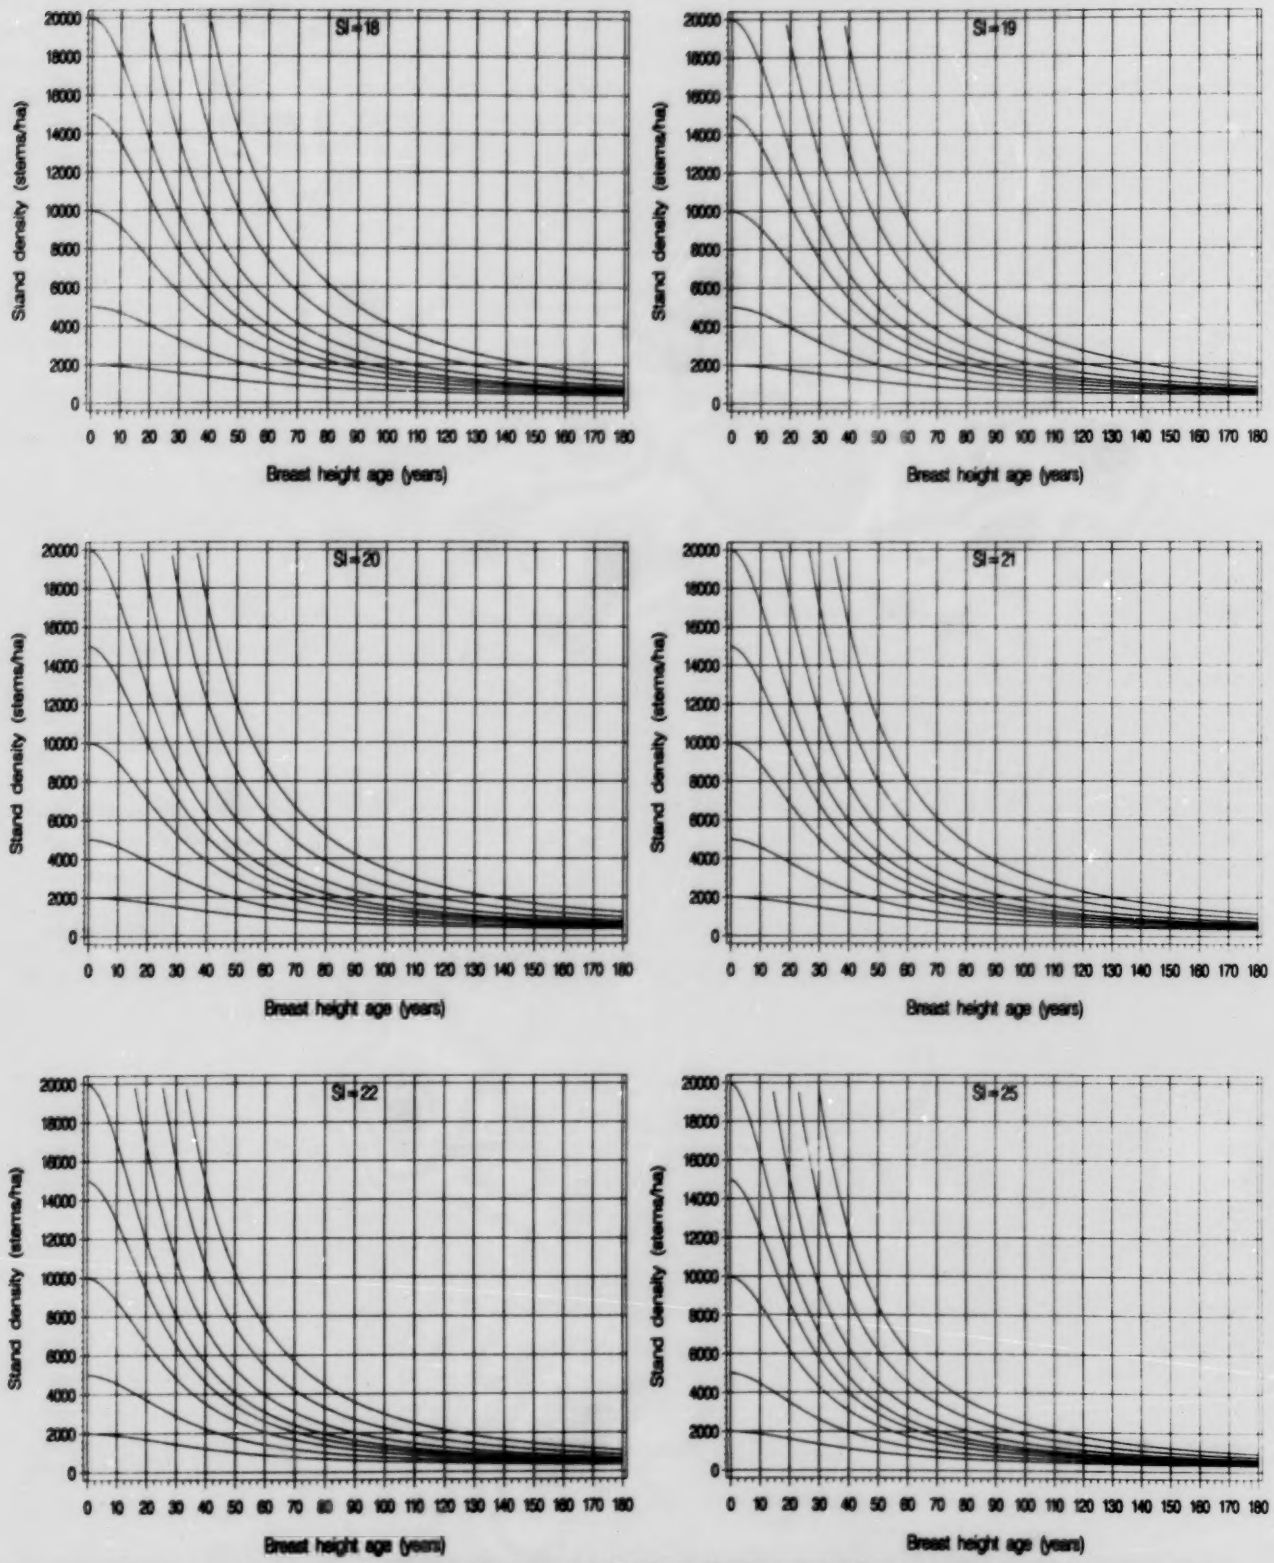

Figure 5. Example mortality curves on different sites (continued). Where SI (site index) refers to the top height at 50 years bhage. Eight initial densities are shown in each graph: 2000, 5000, 10000, 15000, 20000, 30000, 50000 and 80000 (stems/ha).

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 2 of 7).

N_0 /ha	Bhage /yrs	Site index (SI, m) at 50 years bhage																			
		5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 3 of 7).

N_0 /ha	Bhage /yrs	Site index (SI, m) at 50 years bhage																				
		5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 4 of 7).

N_0 /ha	Bhage /yrs	Site index (SI, m) at 50 years bhage																			
		5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 5 of 7).

N_0 /ha	Bhage /yrs	Site index (SI, m) at 50 years bhage																			
		5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 6 of 7).

N_0 /ha	Bhage /yrs	Site index (SI, m) at 50 years bhage

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

Table 4. Lodgepole pine stand density projection table (Part 7 of 7).

Note: N_0 = initial density (defined as stems/ha for trees taller than 1.3 m at bhage zero); SI = site index (top height at 50 years bhage); Top height = average height (m) of the 100 largest DBH trees per ha; Stand density values at bhage 50 are stand density factors (SDF).

2.3 The Weibull Diameter Distribution Function

One of the most striking phenomena observed in lodgepole pine stands is the relative smoothness of the cumulative diameter distributions of these stands (see Figures 6 and 7 for examples). The following cumulative Weibull distribution function was found to fit the diameter distribution data quite well:

$$[7] \quad CUM = 1 - \exp\left[-\left(\frac{DBH}{b_0 (H-1.3)^{b_1} N^{b_2} Bhage^{b_3} + b_4 Bhage} \right)^{c_0 \exp[c_1 (H-1.3)] Bhage^{c_2}} \right]$$

where CUM is the cumulative diameter distribution expressed by a number from 0 to 1; DBH (cm) is the tree diameter at breast height; N is the stand density, defined as stems/ha for trees taller than 1.3 m; H is the average height (m) of all trees in the stand taller than 1.3 m; and Bhage is the breast height age of the stand (years). The estimated coefficients are found to be: b_0 = 9.702019, b_1 = 0.796606, b_2 = -0.204526, b_3 = -0.0316423, b_4 = 0.0246783, c_0 = 2.694615, c_1 = 0.0277951, and c_2 = -0.00708821.

The Weibull diameter distribution function [7] was estimated using a one-step parameter prediction method, on the combined diameter distribution data from all sample plots (Huang 2001). The conventional two-step parameter recovery method of fitting separate Weibull distribution to the diameter-class frequency data from each individual plot, and then regressing the estimated parameters to other plot-level variables such as site index and stand density (see Clutter et al. 1983), was found to be less efficient than the one-step parameter prediction approach.

The estimated Weibull function [7] can be partitioned into a distance-independent individual tree model. This involves the use of the "inverse-distribution" approach (Huang 2001), a concept derived from the "inverse-regression" procedure (Draper and Smith 1998). To illustrate, assuming that there are N trees in a 1-ha stand, and the diameters of these trees are known. Based on this assumption and equation [7], the cumulative Weibull diameter distribution function corresponding to the *i*th tree, where i = 1, 2, 3, ..., N, can be written as follows:

$$[8] \quad CUM_i = i \times \frac{1}{N} = 1 - \exp\left[-\left(\frac{DBH_i}{b} \right)^c \right]$$

where 1/N is the relative frequency for each tree in the stand, DBH_i is the diameter at breast height for the *i*th tree, and *b* and *c* are parameters defined in [9]:

$$[9] \quad b = b_0 (H-1.3)^{b_1} N^{b_2} Bhage^{b_3} + b_4 Bhage$$

$$c = c_0 \exp[c_1 (H-1.3)] Bhage^{c_2}$$

Applying the inverse-distribution approach (Huang 2001), DBH_i in equation [8] can be solved inversely to give:

$$[10] \quad DBH_i = b\left[-\ln(1 - CUM_i) \right]^{1/c}$$

Therefore, once the cumulative Weibull distribution function is estimated and the *b* and *c* parameters are known, the diameter of every tree in the stand can be calculated according to [10]. An example calculation is provided in Huang (2001).

In essence, the partitioning of the Weibull function into a tree model involves dividing the function into many narrow diameter classes of unequal intervals, such that there is only one tree in each class.

Because of the way that the Weibull function was partitioned, GYPSY allows for the generation of compatible projections on three levels of detail: whole stand, diameter class and individual tree. Diameter class and stand-level yields are obtained by accumulating the yields of individual trees from the partitioned function. GYPSY's ability to provide individual tree yield estimation without requiring the fit of individual tree models, and all projections generated by GYPSY on three levels of detail are guaranteed to be compatible, can be useful in practical applications.

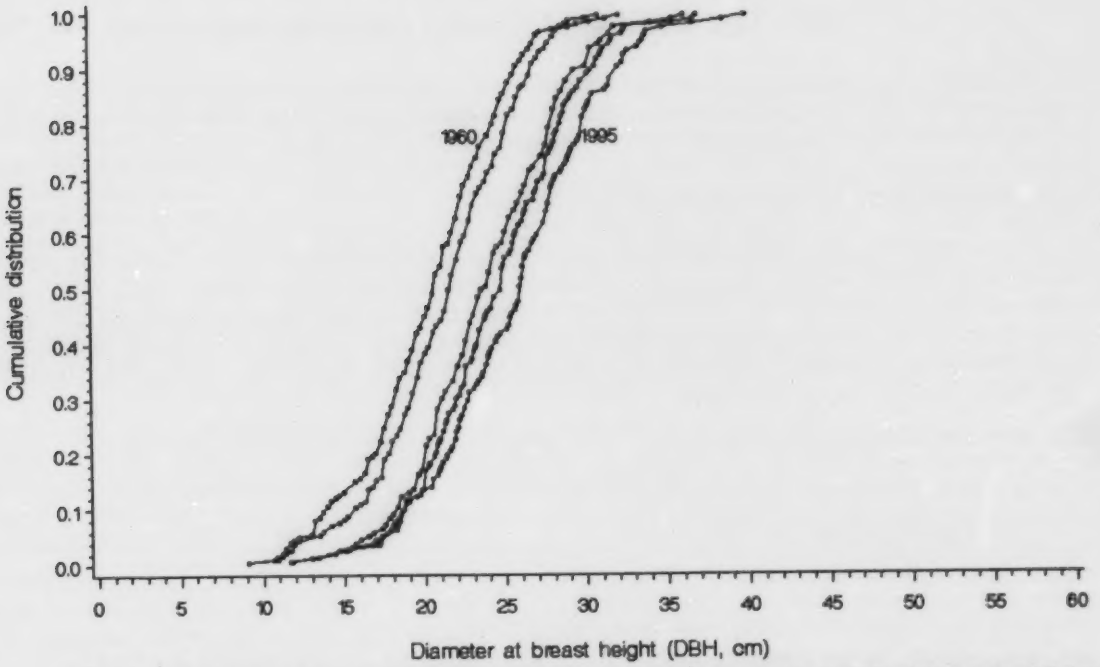

Figure 6. Cumulative diameter distribution curves for an example permanent sample plot measured 5 times over a 35-year period. The curves (from left to right) represent the cumulative diameter distribution at 1960, 1965, 1980, 1985, and 1995, respectively. The dots on each curve represent the actual observations of tree diameter at breast height (DBH).

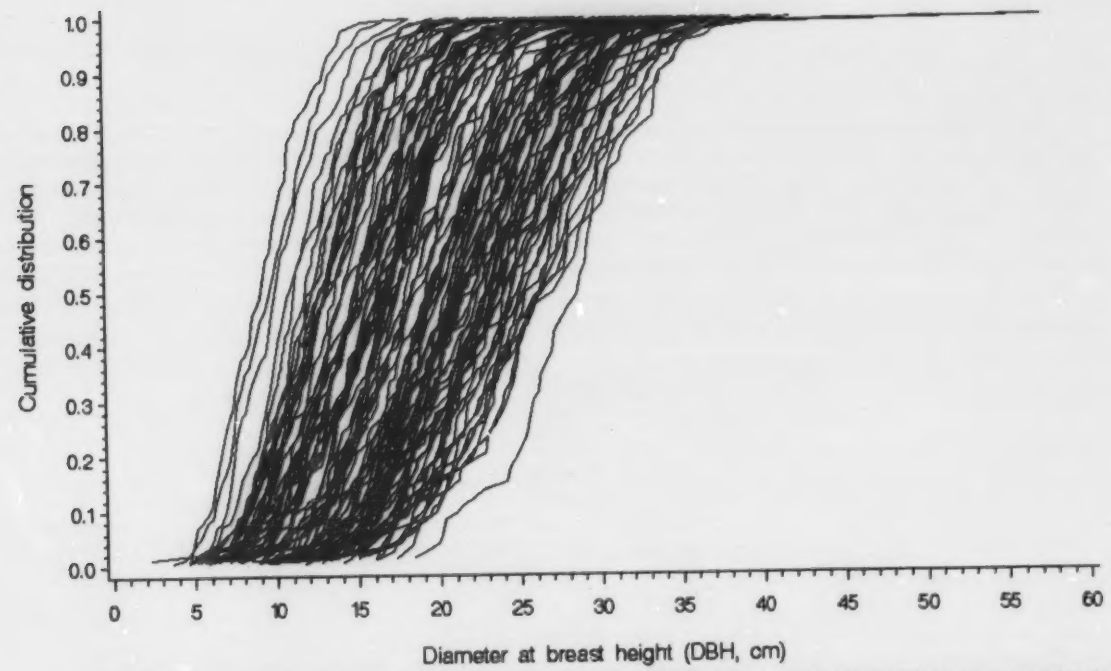

Figure 7. Cumulative diameter distribution curves from 32 permanent sample plots (which correspond to less than 10% of the data used to estimate the Weibull distribution function). Each curve in this graph represents the cumulative diameter distribution for one plot at a specific measurement year.

3.0 The Auxiliary Models and Variables

A number of auxiliary models used in GYPSY for seed-origin natural and regenerated lodgepole pine stands are presented here. These models show the specific relationships among the variables that appear in GYPSY. They can be used to predict various tree and stand characteristics.

3.1 The Individual Tree Height Prediction Model

The most frequently used height prediction models are the so-called "height-diameter" equations, which predict total tree height as a function of tree diameter at breast height (Huang et al. 1992; Huang 1999; Huang et al. 2000a). The predictive capability of the height-diameter equation is typically improved if additional tree and stand variables are added into the equation, such as the inclusion of tree or stand age, stand basal area, competition index, and site productivity (Larsen and Hann 1987; Huang and Titus 1994). The height prediction model developed for lodgepole pine in Alberta takes the following form:

[11] $$Ht = 1.3 + a[1 - \exp(-bDBH)]^c$$

$$a = a_0 (H_{TOP} - 1.3)^{a_1} BA^{a_2} Bhage^{a_3} \exp(-a_4 Bhage)$$

$$c = c_0 \exp[c_1 (H_{TOP} - 1.3)] D_q^{c_2}$$

where: Ht = total tree height (m); DBH = tree diameter (cm) at breast height; H_{TOP} = top height (m), defined as the average height of the 100 largest DBH trees per ha; Bhage = breast height age of the stand (years); BA = total stand basal area (m^2/ha); and D_q = quadratic mean diameter (cm) of the stand. The coefficients are: a_0 = 2.998310, a_1 = 0.539976, a_2 = 0.0476366, a_3 = 0.0970740, a_4 = 0.00146169, b = 0.0734742, c_0 = 0.734763, c_1 = 0.0376660 and c_2 = -0.0568916.

3.2 The Taper Function

A slightly modified version of Kozak's (1988) variable-exponent taper equation (Huang et al. 1999; Huang et al. 2000b), was estimated for lodgepole pine in Alberta:

[12] $$d_i = a_0 D^{a_1} a_2^{\,D} X_i^{\,b_1 z_i^2 + b_2 \ln(z_i + 0.001) + b_3 \sqrt{z_i} + b_4 e^{z_i} + b_5 (D/H)} + \varepsilon_i, \quad with\ X_i = \frac{1 - \sqrt{h_i / H}}{1 - \sqrt{p}}$$

where d_i is the diameter inside bark (cm) at h_i, h_i is the height (m) above ground ($0 \le h_i \le H$), H is the total tree height (m), D is the breast height diameter outside bark (cm), z_i is the ratio h_i/H, p is the relative height constraint, e is the base of the natural logarithm (≈2.7182818), a_0–a_2 and b_1–b_5 are model parameters, and ε_i is the random error term. In earlier applications of the variable-exponent taper equation (Huang 1994b), the relative height constraint (p) was always fixed at 0.225 (p = 0.225). More recent analyses showed that p can be treated as a parameter and estimated as a part of the nonlinear least squares procedure (Huang et al. 1999; Huang et al. 2000b). The taper coefficients (a_0–a_2, b_1–b_5 and p, see Table 5) are obtained for the province as a whole and for four groups of natural subregions defined in Table 10.

Table 5. Estimated coefficients for the taper equation [12].

Parameter	Natural regions and subregions				
	Upper Foothills	Lower Foothills	Rocky Mountains	Boreal Forests	Provincial
a_0	0.879371	0.863582	0.711755	1.172616	0.895570

b_5	0.090963	0.134962	0.070668	0.099513	0.110855
p	0.240571	0.197189	0.366587	0.053975	0.197424

3.3 Merchantable Volume at Any Utilization Standard

In Alberta, the most commonly used utilization standards for merchantable volume are 13/7, 15/10 and 15/11, and the most commonly used stump height is 0.30 m above ground, where 13 or 15 refers to the stump diameter outside bark, and 7, 10 or 11 refers to the top diameter inside bark. With the estimated taper coefficients provided in Table 5 and the diameter inside-outside bark relationship described in Huang (1994b), merchantable volume at any user-defined utilization standard can be computed. The computation involves several steps: 1) specify the utilization standard (e.g., 8/6, 13/7, 13/9, 15/10, 15/11); 2) specify the stump height (e.g., 0.10, 0.15, 0.18, 0.30 m); 3) specify the minimum merchantable length (e.g., 2.44, 3.66 m); 4) calculate the stump diameter inside bark at the specified stump height using the taper equation [12]; and 5) convert the stump diameter inside bark into stump diameter outside bark using the diameter inside-outside bark relationship (Huang 1994b). Once the stump diameter outside bark is obtained, it is compared to the specified utilization standard to determine if a tree is merchantable or not. For merchantable trees, merchantable volume calculations follow those described in Huang (1994b).

The yield relationships displayed in Appendix 1 are based on four utilization standards specified in Table 6: 0/0, 8/6, 13/7 and 15/10, where 0/0 indicates the gross total volume of the stand. By modifying the stump height value and the minimum values for stump diameter outside bark, top diameter inside bark and merchantable length, GYPSY can also be used to generate yield relationships at any other user-specified utilization standard (Huang 2001). Users can input any utilization standard when running ExcelGYPSY.

Table 6. Specifications of the four utilization standards.

Utilization standard	Stump height (m)	Min. stump diameter outside bark (cm)	Top diameter inside bark (cm)	Min. merchantable length (m)
0/0	0.00	0	0	0.00
8/6	0.15	8	6	2.44
13/7	0.30	13	7	2.44
15/10	0.30	15	10	2.44

3.4 Top Height and Stand Height Relationship

The relationship between top height and stand height is shown in Figure 8, where top height refers to the average height of the 100 largest DBH trees per ha, and stand height refers to the average height of dominant and co-dominant trees in the stand.

A model was developed to describe the relationship between top height and stand height:

[13] $$H_{TOP} = a[1 - \exp(-bH_{DC})]$$

where H_{TOP} is top height (m), defined as the average height of the 100 largest diameter trees per ha, and H_{DC} is stand height (m), defined as the average height of dominant and co-dominant trees in the stand. The coefficients are: a = 145.311296 and b = 0.0079641. If stand height is known, top height H_{TOP} can be predicted directly from equation [13]. If top height is known, stand height H_{DC} can be solved inversely from [13] based on the inverse regression procedure descibed by Draper and Smith (1998).

As shown in Figure 8, the relationship between top height and stand height is strong (R^2 = 0.966, where R^2 is the coefficient of determination). On average, top height is approximately 7.39% higher than stand height.

Based on the top height and stand height relationship shown in [13], it is relatively straightforward to demonstrate that the top height–site index equations and the site index prediction tables presented in Section 2.1 can be converted into stand height based site index equations and tables, if the main interest is in stand height. The most important reason that GYPSY concentrates on top height rather than stand height is that the selection of top height trees (largest DBH trees) is objective, consistent and repeatable, whereas the selection of stand height trees (i.e., dominant and co-dominant trees) can sometimes be fairly subjective, inconsistent and unrepeatable (Nicholas et al. 1991).

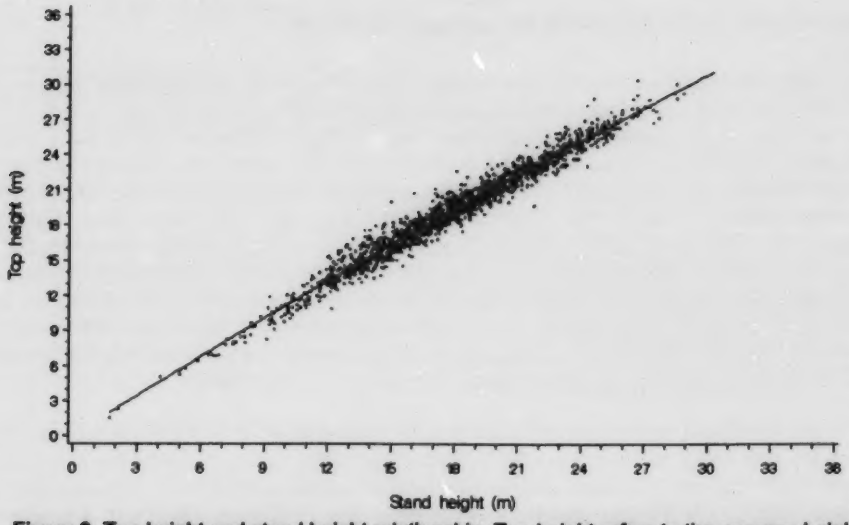

Figure 8. Top height and stand height relationship. Top height refers to the average height of the 100 largest DBH trees per ha. Stand height refers to the average height of dominant and co-dominant trees in the stand. The dots represent the original observations. The fitted line is described by equation [13].

In Alberta, many existing inventories such as the Alberta Vegetation Inventory and Phase 3 Forest Inventory use stand height. The stand height attribute attached to inventory polygon labels is the average height of dominant and co-dominant trees determined by photo interpreters. Based on equation [13], the interpreted stand height can be readily converted into top height.

3.5 Stand Density and Average Height Relationship

Within a reasonable range of stand density, the height growth of dominant and co-dominant trees is not affected (or relatively unaffected) by stand density. This is the most important foundation that the site index concept is built on. However, there are situations in which the height growth is found to be influenced by stand density, particularly with regard to some pine species (Alexander et al. 1967; Monserud 1984). When the average height (of all trees taller than 1.3 m), instead of the dominant and co-dominant height, is considered, the impact of stand density on height growth becomes more profound.

A number of hypothesized potential stand density and height relationships illustrated in Figure 9 were examined. While exceptions existed, it was observed that in general, the average height of lodgepole pine stands is relatively unaffected by low stand density, but when the stand density increases, the height growth gradually slows down, resulting in shorter trees. This scenario is most aptly portrayed by graph (2) of Figure 9. A model that describes the stand density and average height relationship was found to be:

$$[14] \quad H = (SI_{totage} - k) \times \left(\frac{1 + \exp(b_1 + b_2\sqrt{\ln(1+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})}{1 + \exp(b_1 + b_2\sqrt{\ln(1+totage)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})} \right)$$

$$k = (SI_{totage} - 1.3) \times \left[1 - \exp\left(\frac{-c_1 H_{TOP} N_0 \sqrt{SI_{totage}}}{10000} \right) \right]^{\frac{2}{1 + c_2 H_{TOP} + \ln(SI_{totage}^4 + N_0)}}$$

where: H = average height (m) of all trees taller than 1.3 m in the stand; SI_{totage} = total age based site index (m); totage = total age of the stand (years); N_0 = initial density (stems/ha) at bhage zero; H_{TOP} = top height (m), defined as the average height of the 100 largest DBH trees per ha; exp = exponent (≈2.7182818); ln = natural logarithm; b_1 = 10.967495; b_2 = -5.417569; b_3 = -0.167170; b_4 = 0.158292; c_1 = 0.000109527; and c_2 = -0.255312. Three example graphs illustrating the shape of equation [14], are shown in Figure 10.

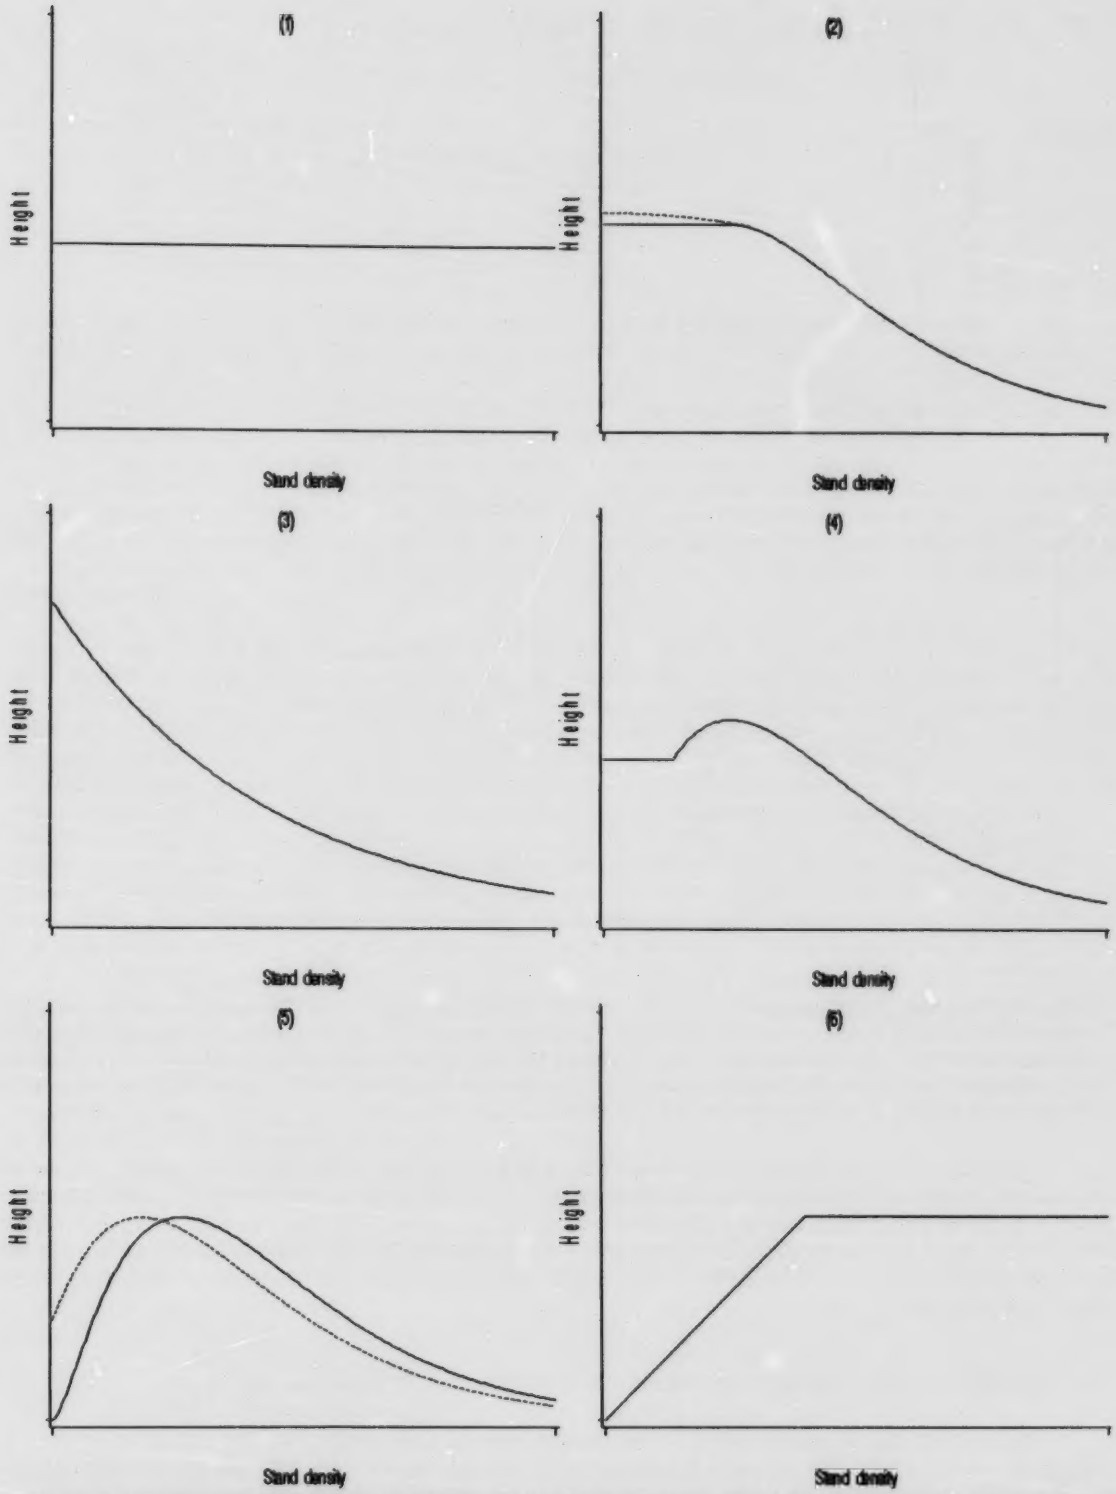

Figure 9. Hypothesized potential stand density and height relationships. Stand density (stems/ha) refers to the total number of trees per ha taller than 1.3 m. Height can refer to the average height of dominant and co-dominant trees, or the average height of all trees taller than 1.3 m in the stand.

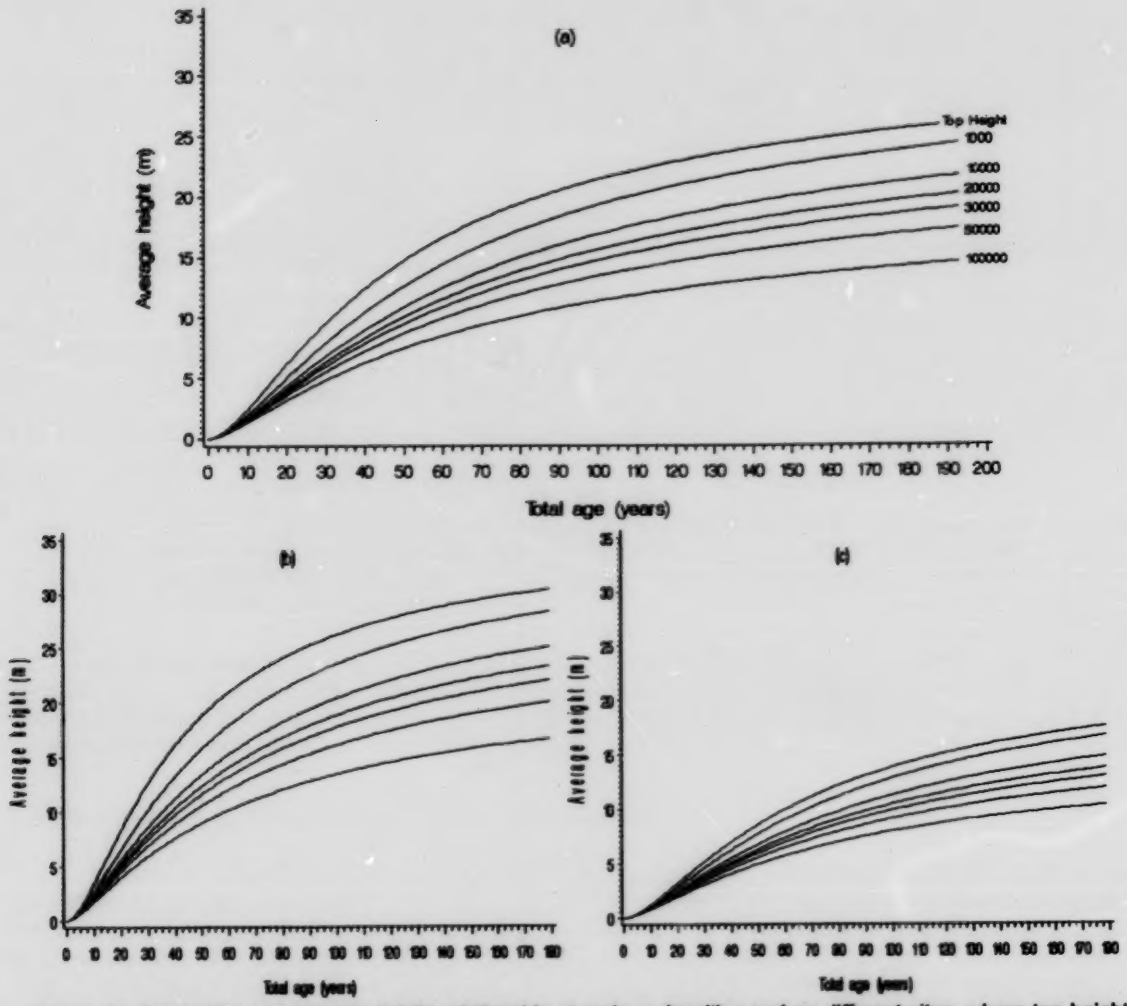

Figure 10. Top height and average height relationship at various densities and on different sites, where top height refers to the average height of the 100 largest DBH trees per ha, average height refers to the average height of all trees taller than 1.3 m in the stand, and 1000, 10000, 20000, 30000, 50000 and 100000 (stems/ha) in graph (a) are initial densities. For graphs (a), (b) and (c), the site index values are 16, 20 and 10 m, respectively. The sequence of the curves appearing in graph (a) also applies to graphs (b) and (c).

Equation [14] implies that on any given site (with a known site index value), top height, defined as the average height of the 100 largest DBH trees per ha, is unaffected by stand density. This complies with the conventional assumption that the site index concept is built upon. The stand density effect in equation [14] is modelled in such a way that it impacts only the average height of all trees in the stand, but not the average height of the 100 largest DBH trees per ha. In the next section, the impact of stand density on top height is evaluated.

3.6 Density-Induced Height Repression and Site Index Realization Ratio

Height repression usually refers to the density-induced slow down of height growth of all trees in the stand. Severe height repression in extremely dense stands may lead to stagnant stands (Mitchell and Goudie 1980; Goudie 1996). In order to assess and quantify the amount of height repression, the following top height and site index relationship, with the stand density effect included, was developed based on the lodgepole pine PSP data:

[15] $$H_{TOP} = (SI_{totage} - k) \times \left(\frac{1 + \exp(b_1 + b_2\sqrt{\ln(1+50)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})}{1 + \exp(b_1 + b_2\sqrt{\ln(1+totage)} + b_3[\ln(SI_{totage})]^2 + b_4\sqrt{50})} \right)$$

$$k = (SI_{totage} - 1.3) \times \left(1 - \exp\left[-\frac{1}{2} \ln\left(SI_{totage} + \frac{N_0}{\sqrt{SI_{totage}}} + \sqrt{N_0} \right) \right] \right)^c$$

$$c = \frac{b_5}{1 + totage/100 + \ln[SI_{totage} + totage^2 + \ln(1+N_0)]}$$

where: H_{TOP} = top height (m), defined as the average height of the 100 largest DBH trees per ha; SI_{totage} = totage based site index (m); totage = total age of the stand (years); N_0 = initial density (stems/ha) at bhage zero; exp = exponent (≈2.718282); ln = natural logarithm; b_1 = 10.967495; b_2 = -5.417569; b_3 = -0.167170; b_4 = 0.158292 and b_5 = 2567.746347. When N_0 = 0, $k \equiv 0$ (k is congruent to zero because $k < 1.0\times10^{-18}$ for $1.3 < SI_{totage} < 30$), which means that [15] reduces to the density-free site index equation [1].

Several example graphs illustrating the density-induced height repression described by equation [15] are shown in Figure 11. It was observed that in general, when the initial density N_0 is less than 10000 stems/ha, there is a marginal (and practically negligible) amount of height repression. When N_0 is less than 5000 stems/ha, the top height trajectory is virtually identical to that obtained using an initial density of zero (see Figure 11).

While the practice of incorporating stand density into the site index model $H_{TOP} = f(SI_{totage}, totage)$ may appear simple and straightforward, it in fact represents a fundamental change in the denifition and the understanding of the site index concept. When $H_{TOP} = f(SI_{totage}, totage, density)$ is used, different densities will, not only lead to different site indices given the same height and age, but also to different heights given the same site index and age. What this means is that, by controlling the density factor, one can increase or decrease the site productivity and get different site index values for the same site. One can also alter the site productivity in the middle of stand development through some silvicultural means such as thinning and selective cutting. Operationally, with $H_{TOP} = f(SI_{totage}, totage, density)$, one can manage the stand density to get an increased site productivity, and consequently, an increased volume production under different stand density management regimes. Of course, one may also decrease the site productivity and get a reduced volume production if a poor stand density management practice was implemented.

Traditionally, site index is a fixed stand attribute by definition, and is assumed to be unaffected (or more or less unaffected) by a wide range of stand density. With the inclusion of the stand density effect in the site index model, site index is no longer a fixed stand attribute, and site productivity as defined by site index can be altered. Clearly, this is contrary to the conventional site index concept, but it is probably more realistic in many practical situations in which stand density exerts a statistically significant impact on height growth. Additional studies in this area may be needed. Currently, equation [15] is used only in the GYPSY version for thinned lodgepole pine stands.

Potential site index, site index realization ratio and height repression index

Based on equation [15], the concepts of potential site index (SIP), realized or observed site index (SIO), site index realization ratio (SIRR), and height repression index (RI) can be established:

[16] $$SIRR = \frac{SIO}{SIP}$$

[17] $$RI = 100\left(1 - \frac{SIO}{SIP}\right) = 100(1 - SIRR)$$

where SIRR is the site index realization ratio, SIO is the observed site index derived from the conventional site index equation $H_{TOP} = f(SI_{totage}, totage)$, and SIP is the potential site index derived from equation [15]. More detailed descriptions of the actual procedures used in calculating SIP, SIO, SIRR and RI, along with the tables listing the calculated results, are provided in Huang (2001).

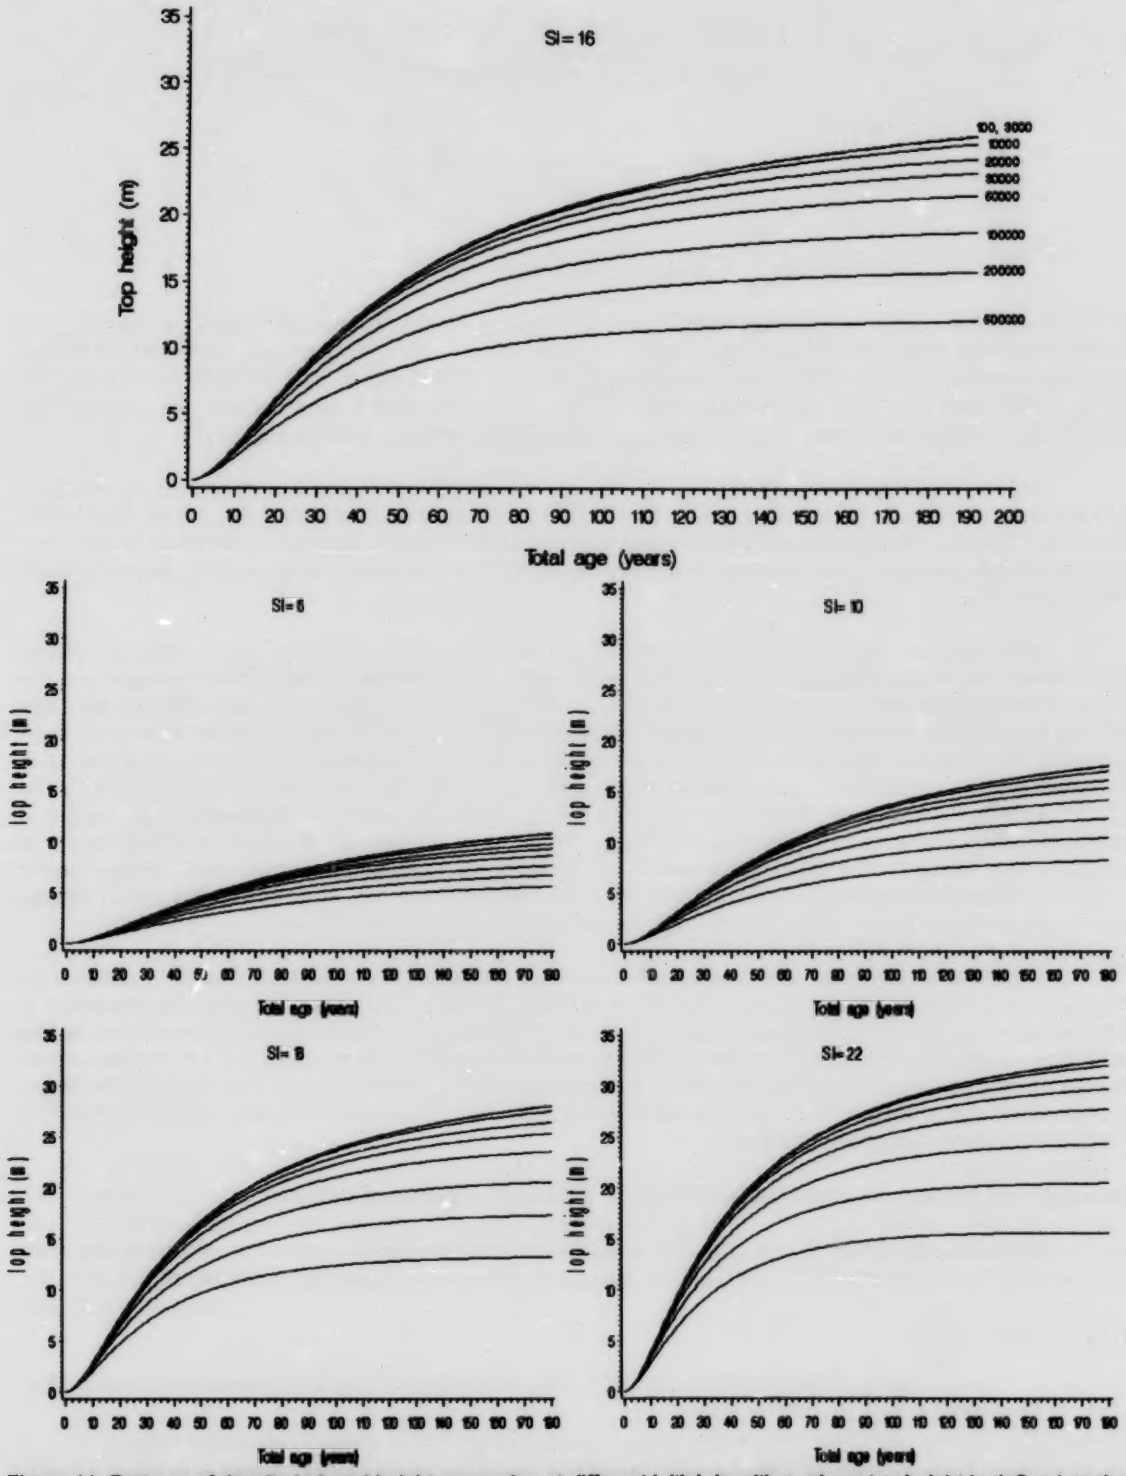

Figure 11. Patterns of density-induced height repression at different initial densities, where top height is defined as the average height (m) of the 100 largest DBH trees per ha. The numbers listed on the right-hand side in the top graph are initial densities (stems/ha). The same initial densities, in the same sequence as shown in the top graph, are used in all graphs. The SI values (16, 6, 10, 18 and 22) refer to the site indices (m) at 50 years bhage.

3.7 The Growth Intercept Model

The most typical method of estimating site index from top height and age requires measurements of top height and one of the three ages (total age, stump age or breast height age). Sometimes, the field measurements on top height and age may be rather time consuming and difficult to obtain, for increment cores and total tree height must be taken. A more efficient approach of estimating site index, especially in young stands, is to use growth intercept or height increment without requiring measurements on total tree height and age. Such a "heightless" and "ageless" site index prediction method possesses some practical advantages as increment cores and top height are no longer needed any more.

Growth intercept (GI) is defined as the periodic height increment (in m/year) above a chosen base height. Often, different growth intercept periods (also termed lengths) such as 3-, 4-, 5- and 10-years, and different but fixed base heights such as 0.3, 0.5, 0.75, 0.8, 1.0, 1.3, 1.5 and 2.0 m above ground, are used (Figure 12). Huang (1994a; 1996) reviewed the historical development of the growth intercept techniques and discussed some of the primary characteristics (e.g., a fixed base height, a fixed growth interval length) and potential incompatibilities associated with the growth intercept models.

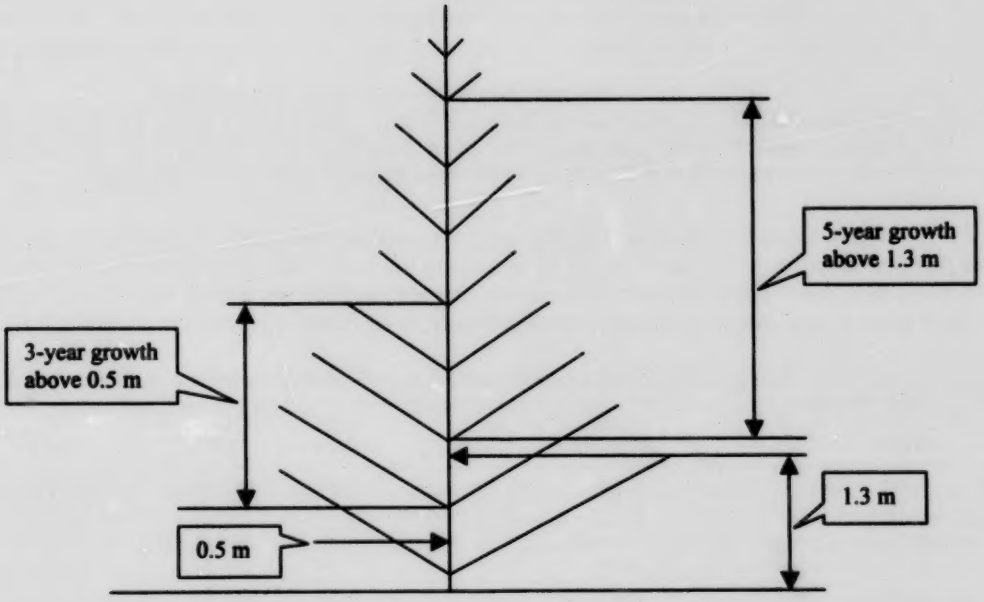

Figure 12. An illustration of growth intercept. Growth intercept (GI) is defined as the periodic height increment (m/year) above a pre-selected base height. On the left is a 3-year growth intercept above the base height of 0.5 m. On the right is a 5-year growth intercept above the breast height. Note that the length of time (e.g., 3-years, or 5-years) and the base height of the growth intercept can be varied.

In GYPSY, the recommended growth intercept to be used is the 5-year growth intercept above 1.3 m, which is illustrated on the right-hand side of Figure 12. The growth intercept model estimated in GYPSY takes the following form:

$$[18] \qquad SI_{bhage} = \frac{GI5}{a + bGI5}$$

where GI5 is the 5-year growth intercept (m/year) above the breast height of 1.3 m above ground, SI_{bhage} is the breast height age based site index, which equals to the top height at 50 years bhage, and top height is defined as the average height of the 100 largest DBH trees per ha. The estimated coefficients for equation [18] are: a = 0.00850048 and b = 0.032694. Figure 13 shows the fitted growth intercept model overlaid on the original plot data used to estimate the model.

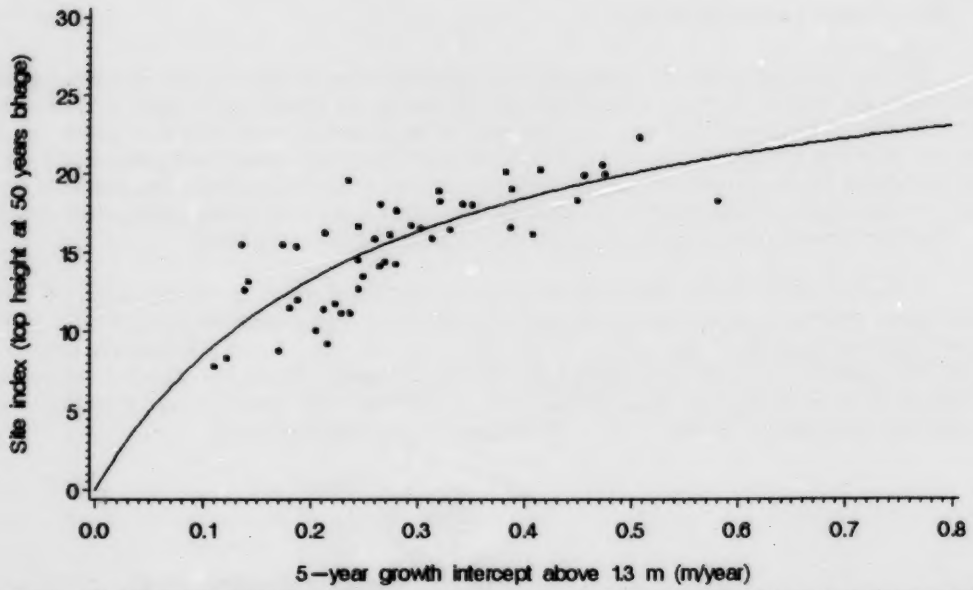

Figure 13. Relationship between site index and 5-year growth intercept above 1.3 m. Site index is defined as the top height (m) at 50 years bhage. The curve is described by model [18]. Each dot represents an original observation obtained from three largest DBH trees sectioned longitudinally in each plot.

Table 7 lists the predicted site indices at different values of GI5. To predict the site index of a plot, a plot-based GI5 can first be obtained by averaging the three GI5s from three largest DBH trees in each 0.03-ha plot. A corresponding site index for the plot is then obtained directly from Table 7. A more detailed description on the use of the growth intercept model for site index prediction is provided in Huang (2001).

Table 7. Site index predictions based on 5-year growth intercepts above 1.3 m.

GI5 (m/year)	SI (m)	GI5 (m/year)	SI (m)	GI5 (m/year)	SI (m)	GI5 (m/year)	SI (m)
0.00	0.00	0.26	15.29	0.51	20.26	0.76	22.79

0.21	13.67	0.46	19.54	0.71	22.39	0.96	24.07
0.22	14.02	0.47	19.69	0.72	22.47	0.97	24.12
0.23	14.36	0.48	19.84	0.73	22.55	0.98	24.17
0.24	14.68	0.49	19.98	0.74	22.63	0.99	24.22
0.25	14.99	0.50	20.12	0.75	22.71	1.00	24.27

Note: GI5 is the 5-year growth intercept (m/year) above 1.3 m. SI is the bhage based site index, which equals to the top height (m) at 50 years bhage. To predict the site index of a plot, a plot-based GI5 can first be obtained by averaging the three GI5s from three site (largest DBH) trees in each 0.03-ha plot. The site index value for the plot is then read directly from this table.

3.8 Estimating Stand Height from Top Height and Average Height

Based on the data from permanent sample plots, a model was developed to estimate stand height from top height and average height:

$$[19] \quad H_{DC} = H + \frac{H_{TOP} - H}{1 + \frac{b}{H^c}}$$

where: H_{DC} is stand height (m), defined as the average height of dominant and co-dominant trees in the stand; H_{TOP} is top height (m), defined as the average height of the 100 largest DBH trees per ha; and H is average height (m), defined as the average height of all trees taller than 1.3 m in the stand. The estimated coefficients for [19] are: b = 0.172967 and c = -0.386941.

Once the values for top height and average height are known, stand height can be predicted from equation [19]. The stand height value predicted from [19] is bounded between the average height (H) and the top height (H_{TOP}) of a stand.

3.9 Mean Annual Increment

Mean annual increment (MAI) refers to the average annual volume growth up to any given age. It applies to gross total volume as well as to merchantable volumes at different utilization standards. MAI is calculated as the volume attained at any age divided by the age. In practice, total age is more commonly used when dealing with MAI.

An expression used to calculate MAI can be written as follows:

$$[20] \quad MAI = \frac{V_{totage}}{totage}$$

where MAI is the mean annual increment (m^3/ha/year) associated with V_{totage}, V_{totage} can be the gross total volume or merchantable volume at any specified utilization standard (m^3/ha), and totage is the total age of the stand (years).

The calculation of MAI at different ages has a special meaning in forest management. The age at which the MAI reaches the maximum is usually referred to as the age of maximum MAI. It has some very important management implications, and represents the biological rotation age at which maximum volume growth is achieved.

3.10 Maximum Stand Density and Stand Density Index

Stand density index (SDI) is a concept initiated by Reineke (1933). It is based on the limiting (or maximum) relationship between stand density and average stand diameter (or quadratic mean diameter). For lodgepole pine stands in Alberta, this limiting relationship was found to be:

$$[21] \quad N_{max} = \frac{b_1}{1 + \exp[b_2 + b_3 \ln(1 + D)]} - D$$

where N_{max} is the maximum stand density (stems/ha) at any given D, and D is the arithmetic average stand diameter (cm). The estimated coefficients are: b_1 = 84530.89161, b_2 = -2.33386, and b_3 = 1.92012. Both the PSP data and the provincial temporary sample plot (TSP) data for lodgepole pine stands were used in deriving the estimates for [21]. Figure 14 shows equation [21] overlaid on the original data from PSPs and TSPs.

The maximum density-size relationship expressed in [21] was developed based on the boundary analysis on the density-size observations shown in Figure 14. The conventional method of developing an

average density line based on the density-size data from vaguely defined "fully-stocked" stands, and then labelling this average density line as the maximum density line, is not really pertinent. The *average* density line obtained from "fully-stocked" stands is quite different from the *maximum* density line obtained through boundary analysis.

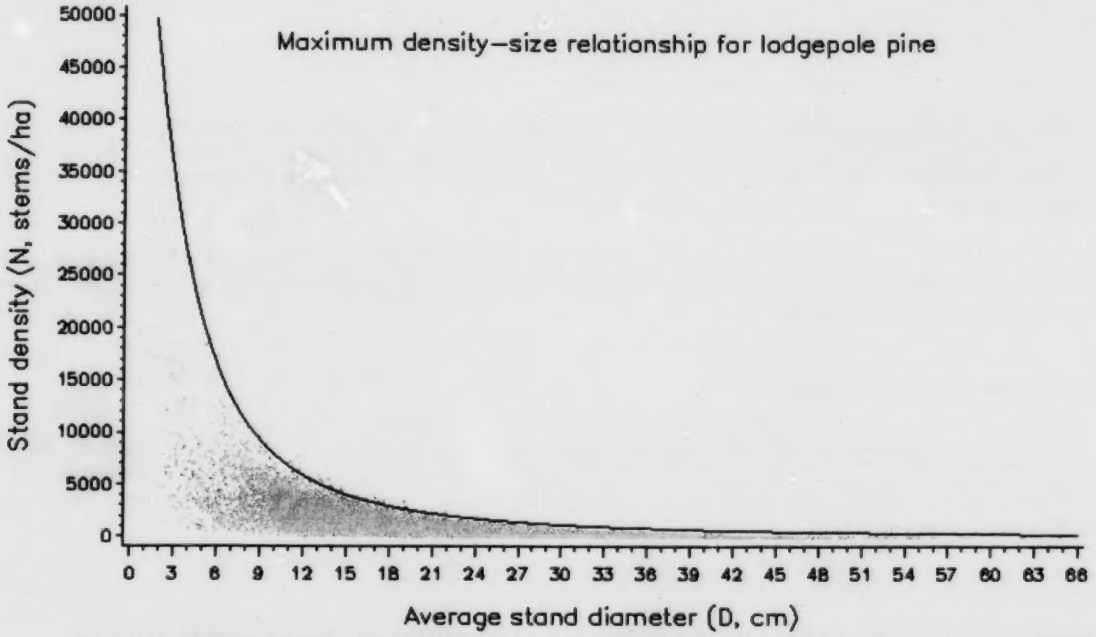

Figure 14. Maximum density-size relationship for lodgepole pine stands in Alberta. The maximum density line is described by equation [21]. Each dot in this graph represents an original density-size observation from one permanent or temporary sample plot.

The logarithmic transformation procedure, typically seen in developing density–size relationships, was not used when estimating equation [21]. The direct estimation of [21] in its original form eliminated the biases associated with the logarithmic transformation, and allowed the results to be interpreted directly on original data, rather than on transformed data.

If the maximum stand density index (SDI_{max}) is defined as the expected maximum number of trees per ha when D equals to 10 cm, equation [21] can be re-written as:

$$[22] \quad SDI_{max} = \frac{b_1}{1+\exp[b_2 + b_3 \ln(1+10)]} - 10$$

Isolating b_1 from [22] gives:

$$[23] \quad b_1 = (SDI_{max} + 10)(1+\exp[b_2 + b_3 \ln(1+10)])$$

Substituting [23] into [21] produces:

$$[24] \quad N_{max} = \frac{(SDI_{max} + 10)(1+\exp[b_2 + b_3 \ln(1+10)])}{1+\exp[b_2 + b_3 \ln(1+D)]} - D$$

Re-arranging [24] for SDI_{max} gives:

$$[25] \quad SDI_{max} = (N_{max} + D) \times \left(\frac{1+\exp[b_2 + b_3 \ln(1+D)]}{1+\exp[b_2 + b_3 \ln(1+10)]} \right) - 10$$

Therefore, for any stand of known density (N) and average diameter (D), the stand density index (SDI) can be computed by:

$$[26] \quad SDI = (N + D)\left(\frac{1+\exp[b_2 + b_3 \ln(1+D)]}{1+\exp[b_2 + b_3 \ln(1+10)]}\right) - 10$$

where: SDI = stand density index (which refers to the expected number of trees per ha when D = 10 cm), D = arithmetic average stand diameter (cm), and N = stand density (stems/ha), defined as the total number of trees per ha taller than 1.3 m. The SDI value calculated from [26] can be used to compare two stands with different densities and average diameters to determine which stand is relatively denser. It can also be compared to the SDI_{max} value from [25] to determine the relative stocking of a stand.

For practical purposes, the SDI value calculated from equation [26] can be grouped into one of the three broad density classes defined in Table 8. Stocking can then be determined approximately based on the SDI ranges and some silvicultural and management considerations.

Table 8. Stand density classes and stockings for lodgepole pine in Alberta.

Density class (DC)	SDI ranges (stems/ha)	Definition	Stocking
1	0 < SDI < 2500	Low	Under-stocked
2	2500 ≤ SDI < 4500	Medium to high	Fully-stocked
3	4500 ≤ SDI	Very high	Over-stocked

Note: SDI is stand density index, defined as the stand density (stems/ha) at a reference average stand diameter of 10 cm.

Reineke's (1933) stand density index is one of most frequently referenced stand density measures in growth and yield studies and silvicultural research. It was based on the limiting relationship between the number of trees and the average tree size observed in "fully-stocked" stands. As seen from the above SDI formulation implemented in GYPSY, several changes were made to Reineke's (1933) stand density index. The main objective of these changes was to take out some of the potential ambiguities associated with the original derivation of SDI. Several conceptual modifications to the original SDI were also made in GYPSY. They are discussed in Huang (2001).

3.11 Maximum Mean Tree Volume and Relative Density Index

Relative density index (RDI) is a concept initiated by Drew and Flewelling (1979). It is very similar to the stand density index developed by Reineke (1933). RDI is based on the so-called -3/2 power law of self-thinning that describes the limiting relationship between mean tree volume and stand density (number of trees per ha).

A graph showing the original mean tree volume and stand density observations from permanent and temporary sample plots is displayed in Figure 15. A model describing the limiting relationship between mean tree volume and stand density was found to be:

$$[27] \quad v_{max} = \frac{b_1}{1+\exp[b_2 + b_3 \ln(N+200)]}$$

where v_{max} is the expected maximum mean tree volume (m^3/tree) at a given stand density, N is the stand density (stems/ha), defined as the total number of trees taller than 1.3 m, and b_1, b_2 and b_3 are coefficients (b_1 = 3.633481, b_2 = -8.724372 and b_3 = 1.417380). The mean tree volume refers to the arithmetic average gross total volume per tree at the 0/0 utilization standard defined in Table 6.

Figure 15 shows the maximum mean tree volume–density line generated from [27] overlaid on the original mean tree volume and stand density observations. It may be worthwhile to note that the maximum density line shown in Figure 15 is not the same as the conventional "maximum density line" obtained from vaguely defined "fully-stocked" stands (Huang 2001).

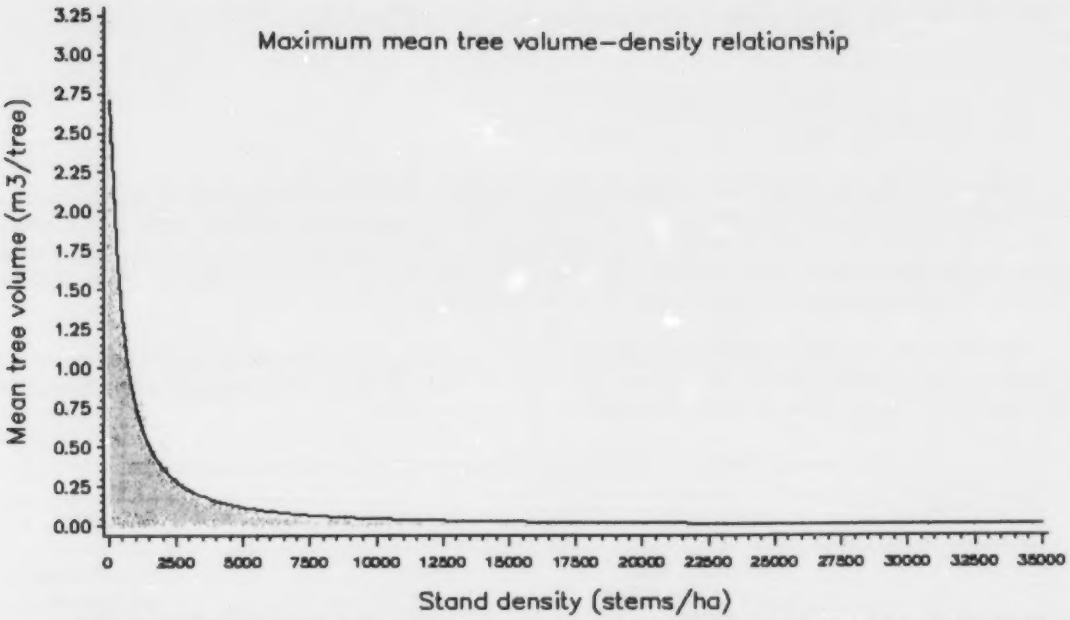

Figure 15. Maximum mean tree volume and stand density relationship for lodgepole pine in Alberta. Mean tree volume refers to the average gross total volume per tree (m^3/tree). Stand density refers to the number of trees per ha taller than 1.3 m. The maximum mean tree volume-density curve is described by equation [27]. Each dot in this graph represents an original volume-density observation from one sample plot.

Based on equation [27], for any stand with a known mean tree volume of *v* and a known density of N, the maximum density that this stand can support, N_{max}, can be obtained by re-writing equation [27] into:

$$[28] \quad v = \frac{b_1}{1+\exp[b_2 + b_3 \ln(N_{max} + 200)]}$$

Isolating N_{max} from [28] gives:

$$[29] \quad N_{max} = \exp\left(\frac{[\ln(b_1 / v - 1) - b_2]}{b_3}\right) - 200$$

The RDI is defined as the ratio between the observed stand density of the subject stand and the maximum density attainable in a stand with the same mean tree volume as the subject stand:

$$[30] \quad RDI = \frac{N}{N_{max}} = \frac{N}{\exp\left(\frac{[\ln(b_1 / v - 1) - b_2]}{b_3}\right) - 200}$$

where N is the density (stems/ha) of the subject stand, *v* is the mean tree volume (m^3/tree) of the subject stand, and N_{max} is the maximum stand density attainable in a stand with the same mean tree volume as the subject stand. To calculate the RDI value for a subject stand, the mean tree volume and the density of the stand must be obtained. With the known mean tree volume, the maximum stand density attainable in a stand with the same mean tree volume as the subject stand is predicted from equation [29], and the RDI value is calculated from equation [30].

The RDI concept associates stand density with mean tree volume. It was used as the foundation for creating stand density management diagrams and developing commercial and pre-commercial thinning strategies (Drew and Flewelling 1979). If necessary, stand density management diagrams can be created based on the models developed in GYPSY.

As a general guide for lodgepole pine stands in Alberta, an RDI value of less than 0.20 commonly characterizes open-grown stands in which crown closure is unlikely to occur. An RDI value of 0.20 to 0.50 generally characterizes fully-stocked stands in which crown closure is very likely to occur. An RDI value of greater than 0.50 typically symbolizes over-stocked stands in which crown closure occurs, the competition-induced mortality increases, and the growth of individual trees slows down. An RDI value of equal to, or in rare cases, greater than 1.0 represents the maximum density attainable.

3.12 Average Diameter, Quadratic Mean Diameter and Total Basal Area

Average diameter (D) refers to the arithmetic average stand diameter for all trees taller than 1.3 m in the stand. Quadratic mean diameter (D_q) is defined as the diameter of the tree of mean basal area. Total basal area (BA) is defined as the cumulative cross-sectional area per ha, of tree stems measured at 1.3 m above ground. The relationship between D and D_q is determined by the spread of the individual diameter values within the stand. It can be expressed by:

$$[31] \quad D_q = \sqrt{\frac{1}{N}\sum_{i=1}^{N} DBH_i^2} = \sqrt{\left(\frac{N-1}{N}\right)s^2 + D^2}$$

where: D_q is the quadratic mean diameter (cm), DBH_i is the breast height diameter (cm) for the ith tree (i = 1, 2, 3, ..., N), N is the total number of trees, D is the arithmetic average stand diameter (cm), and s^2 is the sample variance of the DBH_i values calculated by:

$$[32] \quad s^2 = \frac{\sum_{i=1}^{N}(DBH_i - D)^2}{N-1}$$

If the individual diameter values within the stand are unknown, the following equation can be used as a good approximation for the relationship between D and D_q:

$$[33] \quad D_q = a + bD$$

where the coefficients are: a = 0.542314, and b = 1.003845. Equation [33] can be used to predict D_q when D is known. It can also be solved inversely to predict D when D_q is known:

$$[34] \quad D = \frac{D_q - a}{b}$$

The total basal area of a stand can be computed by:

$$[35] \quad BA = N \times \pi(D_q/200)^2 \quad or \quad BA = \frac{\pi}{40000}\sum_{i=1}^{N} DBH_i^2$$

where: BA = total basal area of a stand (m^2/ha), N = stand density (stems/ha), and $\pi \approx 3.14159265358979$.

3.13 Crown Area, Crown Width and Crown Radius

Assuming that the crowns of lodgepole pine trees are circular in shape, crown area refers to the circular area at the base of the live crown. It equals the ground area covered by a vertical projection of tree crown onto the ground. An equation was developed to predict the crown areas for seed-origin natural and regenerated lodgepole pine trees:

$$[36] \quad CA = \frac{1}{3} + aDBH^b$$

where CA is the crown area of the tree (m^2), DBH is the tree diameter at breast height (cm), a = 0.0285387 and b = 1.7647425.

The crown area prediction equation [36] has some limitations. Ideally, because stand density and site quality have considerable influence on crown development, a better predictive relationship could have been established if a stand density measure and a site quality measure were included in [36]. However, because most of the crown measurement data available in Alberta do not relate directly to density and site measures, an improved regression equation with the density and site effect incorporated into it cannot be established. Efforts are presently underway to collect density and site data. It is expected that a different crown area prediction model will be developed once more data are collected.

Since the crown area is assumed to be circular in shape, the following expression exists:

$$[37] \quad CA = \pi \times \left(\frac{CW}{2}\right)^2$$

where CA is the crown area (m^2) predicted from equation [36], and CW is the crown width (m) at the base of the live crown. Crown width is sometimes called crown diameter (m).

By re-arranging equation [37], an expression for CW can be obtained:

$$[38] \quad CW = 2 \times \sqrt{\frac{CA}{\pi}}$$

If crown radius is required, crown radius equals to the crown width divided by 2 (crown radius = CW/2).

3.14 Percent Crown Cover and Crown Closure Class

Percent crown cover is defined as the percentage of ground area covered by a vertical projection of tree crown areas onto the ground. It has also been frequently referred to as crown closure (CC) percent. Percent crown cover is a stand density measure commonly used in photo-based inventories such as the Alberta Vegetation Inventory (Alberta Environmental Protection 1991).

Once the crown area prediction equation [36] is established, and assuming that the impact of the over-lapping crowns is accounted for by [36], the CC value for a stand of N trees/ha can be computed by:

$$[39] \quad CC = \frac{CA_1 + CA_2 + \cdots + CA_N}{10000} \times 100\%$$

where CC is the percent crown cover, N is the stand density (stems/ha), CA_i is the crown area (m^2) for the ith tree (i = 1, 2, 3, ..., N), and 10000 (m^2) is the area of 1-ha. The CC value obtained from [39] can exceed 100% for dense, over-stocked stands.

The CC value computed from equation [39] represents an approximation of the true crown closure percent observed in a photo-based inventory. In order to obtain accurate CC values in a non-photo-based inventory, crown areas of the trees and the spatial distribution of these trees in the stand must be known. At this stage, however, GYPSY does not deal explicitly with the spatial distribution of individual trees in the stand, so an assumption about the spatial distribution of the trees in the stand was made. This assumption presumes that the impact of the over-lapping crowns is accounted for by equation [36]. This is undoubtedly a compromising assumption and one can find reasons and situations in which this assumption may not be valid, especially for stands growing at high densities. While Alberta has lots of data with measurements on every tree's azimuth and distance to plot centre available, and it is possible to develop a spatially explicit model based on these data, the spatial component is nevertheless ignored in this version of GYPSY for a number of reasons (Huang 2001).

In practice, the crown closure percent calculated according to equation [39] can be grouped into one of the five crown closure classes listed in Table 9. These crown closure classes were originally defined in the Alberta Vegetation Inventory (AVI). They are also routinely referred to as AVI stand density classes. In general, the A and B density classes are considered under-stocked and the C and D density classes are considered fully-stocked. A CC value of no more than 5% is considered non-forest.

Table 9. A classification of the crown closure classes.

Percent crown cover (CC)	Crown closure class (AVI density class)
$0 < CC\% \leq 5$	V (non-forest)
$5 < CC\% \leq 30$	A
$30 < CC\% \leq 50$	B
$50 < CC\% \leq 70$	C
$70 < CC\%$	D

3.15 Crown Competition Factor

Crown competition factor (CCF) is a stand density measure that is based on the vertical projection of the crown area of trees of a given diameter relative to the crown area for open-grown trees of the same diameter (Krajicek et al. 1961). It reflects the space occupied by the crown of an average tree in a stand in relation to the maximum space it could occupy if the tree were open-grown.

In order to calculate CCF, the relationship between crown width (CW) and tree diameter at breast height (DBH) must be established from the measurements of open-grown trees. Based on the established relationship, the maximum crown area (MCA), expressed as a percentage on a per ha basis, is calculated for every tree in a stand. The summation of all MCA values on a per ha basis provides the CCF value for the stand. Example calculations of CCF are shown in Krajicek et al. (1961), Clutter et al. (1983), and Avery and Burkhart (1994).

In GYPSY, the following relationship between crown area and tree diameter at breast height was established based on the measurements of open-grown lodgepole pine trees:

$$[40] \quad CA_{open} = \frac{1}{3} + aDBH^{b}$$

where CA_{open} is the crown area (m^2) of an open-grown tree assumed to have a circular crown shape, DBH is the tree diameter at breast height (cm), a = 0.303991, and b = 1.373733. Based on equation [40], the maximum crown area expressed as a percentage of 1-ha, for a tree with a given diameter of DBH_i (i = 1, 2, 3, ..., N), can be calculated as follows:

$$[41] \quad MCA_i = \frac{CA_{open}}{10000} \times 100\% = \frac{1/3 + aDBH_i^{b}}{10000} \times 100\%$$

The CCF value for a stand of N trees/ha is obtained by summing up the MCA_i values calculated for each tree in the stand. In formula form, the expression for CCF is:

$$[42] \quad CCF = \sum_{i=1}^{N} MCA_i = \frac{\sum_{i=1}^{N} (1/3 + aDBH_i^{b})}{10000} \times 100\%$$

where CCF is the crown competition factor on a per ha basis, DBH_i is the tree diameter at breast height for the ith tree (i = 1, 2, 3, ..., N), and N is the number of trees per ha taller than 1.3 m.

Equation [40] can also be used to derive the maximum crown width for open-grown trees (CW_{open}). Since $CA_{open} = \pi(CW_{open}/2)^2$, the following expression can be derived:

$$[43] \quad CW_{open} = 2 \times \sqrt{\frac{CA_{open}}{\pi}}$$

The calculated CW_{open} from [43] can be compared to the CW from [38] to determine the impact of density and competition on crown development. If necessary, a crown competition index can be developed as the ratio between CW and CW_{open}.

As a general guide for lodgepole pine in Alberta, a CCF value of less than 100 often characterizes open-grown stands. Fully-stocked stands typically have an approximate CCF value between 180 and 250. At a CCF value of about 250 to 450, stand growth gradually slows down and thinning or selective cutting may be desirable. A CCF value of greater than 450 usually characterizes slow growth or repressed stands. The ability of lodgepole pine to respond to thinning or other forms of release is reduced substantially when CCF exceeds 450.

3.16 Height to Live Crown

Height to live crown is defined as the distance from the ground to the base of a tree's live crown. The following relationship was established to predict height to live crown:

$$[44] \quad HTC = \frac{Ht \times DBH}{b_0 Ht^{b_1} DBH^{b_2} BA^{b_3} N^{b_4} + DBH}$$

where: HTC = height to live crown (m), Ht = total tree height (m), BA = total stand basal area (m^2/ha), DBH = tree diameter at breast height (cm), and N = stand density (stems/ha). The estimated coefficients are: b_0 = 1.954221, b_1 = -1.125309, b_2 = 2.049099, b_3 = -0.601320, and b_4 = 0.118517.

3.17 Crown Length and Crown Ratio

Crown length (CL) refers to the length of the live crown. It is calculated as the difference between total tree height and height to live crown:

$$[45] \quad CL = Ht - HTC$$

where Ht is total tree height (m), and HTC is height to live crown (m) from [44].

Crown ratio (CR) of a tree is defined as the ratio between crown length and total tree height. It is computed by:

$$[46] \quad CR = \frac{CL}{Ht} = \frac{Ht - HTC}{Ht}$$

where CL is the crown length from [45] and HTC is the height to live crown from [44]. Crown ratio may also be expressed as a percentage value:

$$[47] \quad CR\% = \frac{CL}{Ht} \times 100\% = \frac{Ht - HTC}{Ht} \times 100\%$$

Since $0 \le HTC \le Ht$, it follows that $0 \le CR \le 1$, or $0\% \le CR\% \le 100\%$.

3.18 Slenderness Coefficient

Slenderness coefficient (SLC) of a tree refers to the ratio in percentage between tree height and tree diameter:

$$[48] \quad SLC_i = \frac{Ht_i}{DBH_i} \times 100\%$$

where SLC_i = slenderness coefficient for the ith tree (i = 1, 2, 3, ..., N), DBH_i = diameter at breast height for the ith tree (cm), and Ht_i = total height for the ith tree (m). An average slenderness coefficient for a stand of N trees/ha can be computed by:

$$[49] \quad SLC = \frac{1}{N} \sum_{i=1}^{N} SLC_i$$

where SLC is the average slenderness coefficient for the stand, and SLC_i is the slenderness coefficient for the ith tree in the stand (i = 1, 2, 3, ..., N). Slenderness coefficient is a quantity commonly associated with thinning and wind firmness studies (Navratil 1995; Wang et al. 1998).

3.19 Average Distance Between Trees and Spacing Index

Assuming that a square spacing is used, the average distance between trees can be computed as follows:

$$[50] \quad ADT = \sqrt{\frac{10000}{N}}$$

where ADT is the average distance between trees (m), 10000 (m^2) is the area of 1-ha, and N is the stand density (stems/ha).

Spacing index is also frequently referred to as relative spacing. It is defined as the ratio of average distance between trees to the average height of dominant and co-dominant trees in the stand. If a square spacing is assumed, spacing index or relative spacing (RS) can be computed by:

$$[51] \quad RS_{DC} = \frac{ADT}{H_{DC}} = \frac{\sqrt{10000/N}}{H_{DC}}$$

where: ADT is the average distance between trees (m), N is the stand density (stems/ha), and H_{DC} is the average height of dominant and co-dominant trees in the stand (m).

If top height is used, relative spacing can also be defined as the ratio of average distance between trees to top height:

$$[52] \quad RS_{TOP} = \frac{ADT}{H_{TOP}} = \frac{\sqrt{10000/N}}{H_{TOP}}$$

Both RS_{DC} and RS_{TOP} are used in GYPSY.

Relative spacing is a stand density measure developed from the phenomenon that stands judged to have a desirable stocking level shared similar relative spacing values, and all stands of a given species appear to gradually approach a common minimum value of relative spacing as they grow older (Clutter et al. 1983). By re-arranging [51] or [52], this common minimum value can be used to establish the maximum number of trees per ha to be expected at any given stand height or top height:

$$[53] \quad N = \frac{10000}{RS_{DC}^2 H_{DC}^2} \quad or \quad N = \frac{10000}{RS_{TOP}^2 H_{TOP}^2}$$

Beekhuis (1966) and Wilson (1979) found that relative spacing is quite valuable in predicting mortality and establishing thinning schedules. Parker (1978) showed that a combination of the height growth curve (e.g., the site index curve) and the relative spacing curve implicitly defines a mortality/survival curve.

3.20 Relative Density

Relative density (RD) is a stand density measure developed by Curtis et al. (1981):

$$[54] \quad RD = \frac{BA}{\sqrt{D_q}}$$

where BA is the total basal area of a stand (m^2/ha), and D_q is the quadratic mean diameter (cm). RD is the stand density measure used in the Douglas-fir stand simulator DFSIM. It is widely applied in several Pacific Northwest States.

4.0 Provincial and Ecoregion-based Average Yields for Seed-origin Natural and Regenerated Lodgepole Pine Stands

By using the provincial and regionalized models, GYPSY allows for the creation of provincial and regional yield relationships. Average lodgepole pine yields for the province as a whole and for four groups of natural subregions are presented here.

4.1 Grouping of the Natural Regions and Subregions

Natural regions and subregions of Alberta is a map-based classification of the major ecosystems in Alberta (Alberta Environmental Protection 1994). It is very similar to Ecoregions of Alberta. Based on the available data and the distribution ranges of lodgepole pine in Alberta, the natural regions and subregions of Alberta are classified into four broad groups shown in Table 10. With the increasing data collection effort and the continuously improving understanding of ecosystem management, it is expected that these groups will likely be refined in future applications.

Table 10. Groups of natural regions and subegions.

Group	Subregion	Group	Subregion
I (Upper Foothills)	10 – Upper Foothills	IV (Boreal Forests)	1 – Central Mixedwood
II (Lower Foothills)	11 – Lower Foothills		2 – Dry Mixedwood 3 – Wetland Mixedwood 4 – Sub-Arctic
III (Rocky Mountains)	7 – Alpine 8 – Sub-Alpine 9 – Montane		5 – Peace River Lowlands 6 – Boreal Highlands

4.2 The Format for Yield Tables

Yield tables for seed-origin natural and regenerated lodgepole pine stands are shown in Appendix 1. A typical example of such a table, generated from a site index of 16 m and initial densities of 7000 and 7500 stems/ha, is provided in Table 11a. All variables listed in Table 11a are defined in Table 11b.

As illustrated in Table 11a, each yield table has the same title "Yield Tables for Seed-origin Natural and Regenerated Lodgepole Pine Stands". Included in the two shaded lines of each table is the site index and the initial density of the stand. Site index in all tables refers to the top height at 50 years breast height age. Since the differences between natural and regenerated stands are by and large accounted for by the two variables (stand density and site index) incorporated into the models in GYPSY, each table applies to both seed-origin natural and seed-origin regenerated lodgepole pine stands.

The first column from the left-hand side of each table is the breast height age of the stand used in projection (bhage, years). It is arranged in 5-year intervals. The second column is the total age of the stand (totage, years). The conversions between bhage and totage are site-specific. They are determined by the top height-site index relationship (see Section 5.1 for the conversion table). Starting from the third column from the left are the variables associated with the four utilization standards defined in Table 6. Yield tables at other utilization standards can be obtained by modifying the stump height value and the minimum values for stump diameter, top diameter and merchantable length. The yield table generator ExcelGYPSY can be used to create yield tables at any user-specified utilization standard.

The yield tables displayed in Appendix 1 were generated from a combination of fifteen site indices and eighteen initial densities. They represent a small portion of the tables that can be generated from the models developed in GYPSY. Extrapolations of the yield relationships within the given ranges of site index and initial density can be made from the values listed in the tables. Two computer programs, one based on SAS and the other on Microsoft Visual Basic, can be used to generate yield tables at other combinations of site index, initial density and utilization standard.

Bh age	Total age	Utilization standard (Util. std.) = 0/0 (total volume)																										Util. std. = 8/6				Util. std. = 13/7				Util. std = 15/10

(1) — **Bhage**: breast height age of the stand (years)

(2) — **Totage**: total age of the stand (years)

(3) — **N**: total number of trees per ha taller than 1.3 m (stems/ha)

(4) — **D_q**: quadratic mean stand diameter (cm)

(5) — **D**: arithmetic average stand dismeter (cm)

(6) — **H**: Average height of of all trees taller than 1.3 m (m)

(7) — **H_{DC}**: Stand height (average height of dominant and co-dominant trees, m)

(8) — **H_{TOP}**: top height (average height of the 100 largest DBH trees per ha, m)

(9) — **CW**: crown width or crown diameter (m)

(10) — **CLen**: crown length (m)

(11) — **HTC**: height to live crown (m)

(12) — **CR**: crown ratio

(13) — **CA**: crown area (m^2/tree)

(14) — **BA**: total stand basal area per ha (m^2/ha)

(15) — **SLC**: slenderness coefficient

(16) — **ADT**: Average distance between trees (m)

(17) — **RS_{DC}**: relative spacing (or spacing index) based on stand height

(18) — **RS_{TOP}**: relative spacing (or spacing index) based on top height

(19) — **RD**: relative density

(20) — **RDI**: relative density index

(21) — **SDI**: stand density index

(22) — **SDF**: stand density factor, defined as stems/ha at 50 years bhage

(23) — **CCF**: crown competition factor

(24) — **CC**: percent crown cover

(25) — **Den**: AVI crown closure class or density class (V, A, B, C, D)

(26) — **TPR**: Timber productivity rating

(27) — **V/tree**: gross total volume per tree (m^3/tree)

(28) — **V/ha**: gross total volume per ha (m^3/ha)

(29) — **Mai**: mean annual increment for gross total volume (m^3/ha/year)

(30) — **N**: merchantable stems per ha at 8/6 utilization standard (stems/ha)

(31) — **D**: average diameter at 8/6 utilization standard (cm)

(32) — **V/ha**: merchantable volume per ha at 8/6 utilization standard (m^3/ha)

(33) — **Mai**: mean annual increment at 8/6 utilization standard (m^3/ha/year)

(34) — **N**: merchantable stems per ha at 13/7 utilization standard (stems/ha)

(35) — **D**: average diameter at 13/7 utilization standard (cm)

(36) — **V/ha**: merchantable volume per ha at 13/7 utilization standard (m^3/ha)

(37) — **Mai**: mean annual increment at 13/7 utilization standard (m^3/ha/year)

(38) — **N**: merchantable stems per ha at 15/10 utilization standard (stems/ha)

(39) — **D**: average diameter at 15/10 utilization standard (cm)

(40) — **V/ha**: merchantable volume per ha at 15/10 utilization standard (m^3/ha)

(41) — **Mai**: mean annual increment at 15/10 utilization standard (m^3/ha/year)

The followings are more detailed definitions for the variables that appearing in the yield tables for seed-origin natural and regenerated lodgepole pine stands:

(1) — **Bhage**: breast height age of the stand (years).
(2) — **Totage**: total age of the stand (years).
(3) — **N**: stand density (stems/ha), defined as the total number of trees per ha taller than 1.3 m.
(4) — D_q: quadratic mean stand diameter (cm), calculated by equation [31].
(5) — **D**: arithmetic average stand diameter (cm).
(6) — **H**: average height of all trees taller than 1.3 m (m).
(7) — H_{DC}: stand height (m), defined as the average height of dominant and co-dominant trees.
(8) — H_{TOP}: top height (m), defined as the average height of the 100 largest DBH trees per ha.
(9) — **CW**: crown width or crown diameter (m).
(10) — **CLen**: crown length (m), defined as the length of the live crown.
(11) — **HTC**: height to live crown (m), defined as the distance from the ground to the base of the live crown.
(12) — **CR**: crown ratio, defined as the ratio between crown length and total tree height.
(13) — **CA**: crown area (m^2/tree), defined as the circular area at the base of the live crown.
(14) — **BA**: total stand basal area per ha for trees taller than 1.3 m (m^2/ha).
(15) — **SLC**: slenderness coefficient (m/cm), defined as the ratio in percentage between tree height and tree diameter at breast height.
(16) — **ADT**: average distance between trees (m), calculated by equation [50].
(17) — RS_{DC}: stand height based relative spacing, calculated by equation [51].
(18) — RS_{TOP}: top height based relative spacing, calculated by equation [52].
(19) — **RD**: relative density, calculated by equation [54].
(20) — **RDI**: relative density index, defined as the ratio between the observed stand density of the subject stand and the maximum stand density attainable in a stand with the same mean tree volume as the subject stand. It is calculated by equation [30].
(21) — **SDI**: stand density index, defined as the expected number of trees per ha when the average stand diameter equals to 10 cm. It is calculated by equation [26].
(22) — **SDF**: stand density factor, defined as the stand density (stems/ha) at a reference bhage of 50 years. It can be solved numerically from equation [5].
(23) — **CCF**: crown competition factor, calculated according to equation [42]. It refers to the sum of the maximum crown areas, each expressed as a percentage of 1-ha, of all trees in the stand.
(24) — **CC**: crown cover expressed as a percentage, calculated by equation [39].
(25) — **Den**: AVI density class (or crown closure class), defined in Table 9.
(26) — **TPR**: timber productivity rating, defined at the bottom of Tables 1, 2 and 3.
(27) — **V/tree**: gross total volume per tree (m^3/tree).
(28) — **V/ha**: gross total volume per ha for all trees taller than 1.3 m (m^3/ha).
(29) — **Mai**: mean annual increment for gross total volume (m^3/ha/year).
(30) — **N**: number of merchantable stems per ha at 8/6 utilization standard (stems/ha).
(31) — **D**: arithmetic average stand diameter at 8/6 utilization standard (cm).
(32) — **V/ha**: merchantable volume per ha at 8/6 utilization standard (m^3/ha).
(33) — **Mai**: mean annual increment at 8/6 utilization standard (m^3/ha/year).
(34) — **N**: number of merchantable stems per ha at 13/7 utilization standard (stems/ha).
(35) — **D**: arithmetic average stand diameter at 13/7 utilization standard (cm).
(36) — **V/ha**: merchantable volume per ha at 13/7 utilization standard (m^3/ha).

(37) — **Mai**: mean annual increment at 13/7 utilization standard (m^3/ha/year).

(38) — **N**: number of merchantable stems per ha at 15/10 utilization standard (stems/ha).

(39) — **D**: arithmetic average stand diameter at 15/10 utilization standard (cm).

(40) — **V/ha**: merchantable volume per ha at 15/10 utilization standard (m^3/ha).

(41) — **Mai**: mean annual increment at 15/10 utilization standard (m^3/ha/year).

The exact specifications for the utilization standards shown in the yield tables are defined in Table 6. If necessary, other variables of interest that are not listed in the yield tables can be generated using the models developed in GYPSY.

To illustrate the use of the yield tables, assuming that on SI = 16 m, a regenerated lodgepole pine stand has an initial density of 7000 stems/ha. At bhage = 80 years, the volumes at 0/0, 8/6, 13/7 and 15/10 utilization standards are 303.9, 291.8, 271.3 and 239.6 (m^3/ha), respectively (see Table 11a).

To use the yield tables without knowing the site index and initial density, current density, top height and one of the three types of age (bhage, totage, stumpage) must be known. Assuming that the observed current stand density N = 1500 (stems/ha), H_{TOP} = 25.5 (m) and bhage = 100 (years). Based on these, site index can be approximated from Table 3 (SI ≈ 19 m), and initial density can be approximated from Table 4 and Figure 5 (N_0 ≈ 15000 stems/ha). With the known SI and N_0, volumes at different utilization standards and bhages can be approximated from the yield tables. Of course, the exact estimations can be obtained following the procedures described in Section 5.2. Other methods of using the yield tables and interpreting the results obtained from the yield tables are described in Huang (2001).

4.3 Average Yields for Seed-origin Natural and Regenerated Lodgepole Pine Stands

Average yields for seed-origin natural and regenerated lodgepole pine stands were obtained for the province as a whole, and for the four broad groups of subregions listed in Table 10. The following initial density (N_0) and site index (SI) values, approximated from the available data collected in existing stands, were used to generate the average yield relationships in different regions.

Average yields for seed-origin natural lodgepole pine stands

1). Provincial: N_0 = 7500 stems/ha and SI = 14 m (Appendix 1, Table A59).
2). Upper Foothills: N_0 = 8000 stems/ha and SI = 14 m (Table 12).
3). Lower Foothills: N_0 = 7000 stems/ha and SI = 16 m (Table 12).
4). Rocky Mountains: N_0 = 8500 stems/ha and SI = 11 m (Table 13).
5). Boreal Forests: N_0 = 5500 stems/ha and SI = 14 m (Table 13).

Average yields for seed-origin regenerated lodgepole pine stands

1). Provincial: N_0 = 7000 stems/ha and SI = 16 m (Appendix 1, Table A77).
2). Upper Foothills: N_0 = 7500 stems/ha and SI = 16 m (Table 14).
3). Lower Foothills: N_0 = 7000 stems/ha and SI = 17 m (Table 14).
4). Rocky Mountains: N_0 = 8000 stems/ha and SI = 13 m (Table 15).
5). Boreal Forests: N_0 = 5500 stems/ha and SI = 16 m (Table 15).

Since most models used in GYPSY were developed on the provincial level, the current version of GYPSY concentrates on a provincial basis. Only the expected average yield relationships are provided on regional bases. In cases where the average yields are needed for subregions that are not shown in Table 10, the yield relationships obtained at the provincial level are recommended for use.

To provide a quick look at how site index and initial density impact the yield relationships, several aggregated summary graphs, describing the yields of total volume and merchantable volumes at different utilization standards at some selected site indices and initial densities, are shown in Huang et al. (2001b). They provide a panoramic view of the yield relationships developed in GYPSY.

Table 12. Average yields for seed-origin **natural** lodgepole pine stands in the Upper Foothills (UFH) and Lower Foothills (LFH) regions.

5.0 GYPSY Applications

There are many different ways that GYPSY can be used to make growth and yield projections for natural and regenerated lodgepole pine stands and to solve practical forest management problems (Huang 2001). Two of the typical scenarios that are most likely to be encountered in practice, are presented here. The input variables required to initiate GYPSY are presented first.

5.1 The Input Variables for GYPSY

In order to run GYPSY for seed-origin natural and regenerated lodgepole pine stands, either one of the following two sets of input variables can be used: (I) initial density and site index; (II) current density, top height and age.

Set I – Initial density and site index

Initial density (N_0) refers to the total number of trees (stems/ha) taller than 1.3 m at bhage zero. Unless otherwise defined, site index (SI) refers to the top height at a reference bhage of 50 years, where top height is defined as the average height of the 100 largest DBH trees per ha. If necessary, conversions between bhage based site index and totage based site index can be made according to Table 16, which is derived from equations [1]-[3].

Table 16. Conversions between breast height age based site index (SI or SI_{bhage}) and total age based site index (SI_{totage}).

From SI_{bhage} to SI_{totage}						From SI_{totage} to SI_{bhage}					
SI_{bhage}	SI_{totage}	SI_{bhage}	SI_{totage}	SI_{bhage}	SI_{totage}	SI_{totage}	SI_{bhage}	SI_{totage}	SI_{bhage}	SI_{totage}	SI_{bhage}

11.0	9.58	20.5	19.31	30.0	29.05	11.0	12.39	20.5	21.66	30.0	30.93

Note: SI_{bhage} = top height (m) at 50 years breast height age (bhage), SI_{totage} = top height (m) at 50 years total age (totage), and top height is defined as the average height of the 100 largest DBH trees per ha.

The first set of input variables (initial density and site index) is often associated with management planning, simulations and comparisons in which the initial density and site index are known (or assumed to be known). Based on the known initial density and site index, growth and yield projections for seed-origin natural and seed-origin regenerated lodgepole pine stands can be made in a fairly straightforward manner, as described in Section 5.2.

Set II – Current density, top height and age

Current density refers to the current observed stand density (in stems/ha) for trees taller than 1.3 m. Top height is defined as the average height of the 100 largest DBH trees per ha. Age can be any one of the three types of age: total age, stump age, or breast height age. In practice, top height and age can be obtained by averaging the heights and ages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot. The recommended age for use is bhage. If necessary, conversions among different ages can be made according to Table 17, which is derived from equations [1]-[3].

Table 17. Site-specific breast height age, stump age and total age conversions.

	Site index (SI_{bhage}, m)																							
	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27
Y2BH	27	21	17	15	13	12	10	10	9	8	8	7	7	6	6	6	5	5	5	5	4	4	4	4
Y2SH	10	8	7	6	5	5	4	4	4	3	3	3	3	3	2	2	2	2	2	2	2	2	2	2

Note: Y2BH = years needed to reach breast height (1.3 m above ground), Y2SH = years needed to reach stump height (0.3 m above ground), totage = bhage + Y2BH = stumpage + Y2SH, SI_{bhage} is the bhage based site index, defined as the top height (m) at 50 years bhage, and top height refers to the average height of the 100 largest DBH trees per ha.

The second set of input variables is most typically associated with the growth and yield projections of existing stands. Actual observations on current density, top height and age must first be obtained from plots placed in existing stands, and then inputted into GYPSY to make forward (or sometimes backward) projections. If the observations are obtained from one stand, the projections become stand-specific. When necessary, GYPSY can also be used to make plot-specific projections (Huang 2001).

Intrinsically, the second set of input variables can be considered the same as the first set of input variables. The observed top height and age can be used to estimate site index from the site index equation [1]. The observed current density and age, along with the estimated site index, can be used to derive initial density through the mortality models [5]-[6].

5.2 Projections Based on Initial Density and Site Index

If initial density and site index are known, growth and yield projections for seed-origin natural and regenerated lodgepole pine stands can be read or interpolated directly from the curves shown in Appendix 1. The steps used to generate the yield relationships shown in Appendix 1 are summarized here:

Step 1 – The bhage based SI is converted into totage based site index SI_{totage}. Once SI_{totage} is available, top height (H_{TOP}) at any given bhage or totage can be derived using equation [1].

Step 2 – With known values of SI_{totage}, N_0 and H_{TOP} at any given age, the average height of all trees in the stand (H), can be obtained from equation [14].

Step 3 – Based on N_0 and SI_{totage}, stand density factor (SDF) can be solved numerically from equation [6]. Once SDF is known, stand density (N) at any given age can be predicted from [5].

Step 4 – Once H and N at any given age are known, the Weibull diameter distribution can be constructed using equation [7]. The DBH of every tree in the distribution can be obtained using equation [10] derived from the inverse-distribution approach (Huang 2001).

Step 5 – Having the diameter of every tree, total stand basal area can be computed. Total height of every tree can be estimated based on equation [11]. With the known values of height and diameter for every tree in the stand, total volume and merchantable volumes at different utilization standards can be derived from the taper equation [12].

5.3 Projections Based on Current Density, Top Height and Age

The GYPSY projection scenario described in Section 5.2 assumes that initial density (N_0) and site index (SI) are known. Sometimes, this assumption can be rather restrictive, for one may not always know what the N_0 and SI are. The procedures described here allow for the projections to be made based on the observed current density, top height and one of the three ages from existing stands, where current density refers to the current observed stand density (stems/ha) for trees taller than 1.3 m, and top height and age can be obtained by averaging the heights and ages of three largest DBH trees in each 0.03-ha plot, or four largest DBH trees in each 0.04-ha plot. The recommended age for use in practice is bhage. If necessary, conversions among different types of age can be made according to Table 17.

Once the current density, top height and bhage are known, the following procedure can be used to make growth and yield projections for seed-origin natural and regenerated lodgepole pine stands:

1). Based on the known values of top height and bhage, site index (SI_{bhage} and SI_{totage}) can be derived numerically from equations [1]-[3], or approximated from Table 3 and Table 16.

2). Given the observed current density, bhage, and the predicted SI_{totage}, stand density factor (SDF) can be solved numerically from the mortality function [5]. Once SDF is available, initial density (N_0) can be predicted from equation [6], or approximated from Figure 5 and Table 4.

3). Having the predicted values of initial density and site index, growth and yield projections for seed-origin natural and regenerated lodgepole pine stands can be read or interpolated directly from the curves shown in Appendix 1.

Most growth and yield projections can be labelled forward projections, that is, the growth and yield information at future times are projected based on the current available information. Sometimes, backward projections are necessary. Backward projections trace back the past growth and yield information from the current information. For instance, in GYPSY, the height growth trajectory can be traced back based on the site index equation [1], and the stand density trajectory can be traced back based on the mortality function [5]. Once the top height and the stand density trajectories are known, the Weibull diameter distribution at any point in time can be reconstructed and the past growth and yield information estimated.

GYPSY's ability to make backward projections can be very useful in many practical circumstances. Backward projections allow a targeted yield at any specified time (e.g., at the rotation age) to be assumed, and the initial or intermediate conditions required to achieve the assumed yield to be identified. This can be very important in establishing density regulations for regeneration standards and developing monitoring protocols for sustainable development (Huang 2001).

To use GYPSY to make growth and yield projections, either one of the two sets of input variables listed in Section 5.1 must be known. At times, however, there are cases in which nothing is known about the seed-origin natural and regenerated lodgepole pine stands, yet for whatever reason, growth and yield projections are needed for these stands. When such situations are encountered, the average initial density and site index values listed in Section 4.3 can be used as the input variables to initiate GYPSY runs.

5.4 GYPSY in Microsoft Excel Environment – ExcelGYPSY

In order to facilitate the understanding and application of GYPSY, a yield table generator termed ExcelGYPSY was developed using the Microsoft Visual Basic Programming System. ExcelGYPSY works in a Microsoft Excel environment. It is not restricted to the Microsoft Windows Operating System. A user's guide for ExcelGYPSY is being prepared and is planned for release at a later date.

At this time, ExcelGYPSY is available only to authorized individuals and organizations. Readers who are interested in obtaining the authorization may contact the Forest Management Division of Alberta Land and Forest Service. It is expected that once the other GYPSY modules are completed, ExcelGYPSY will be made more widely available.

7.0 Appendices

Appendix 1. Yield Relationships for Seed-origin Natural and Regenerated Lodgepole Pine Stands in Alberta

A total of 135 tables are presented in Appendix 1. They were generated based fifteen site indexes (SI = 6, 8, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 22 and 25 m) and eighteen initial densities (N_0 = 800, 1000, 1600, 2000, 3000, 4000, 5000, 6000, 7000, 7500, 8000, 9000, 10000, 15000, 20000, 30000, 50000 and 80000 stems/ha). They represent a small portion of the tables that can be generated using GYPSY. Only the results for the four utilization standards specified in Table 6 are provided here. Approximations of the yield relationships within the given ranges of site index and initial density can be made based on these tables. The exact yield relationships at any given values of site index and initial density can be obtained using ExcelGYPSY.

If site index and initial density are known, growth and yield projections for seed-origin natural and regenerated lodgepole pine stands can be read or interpolated directly from the tables shown in Appendix 1. If both site index and initial density are unknown, they must first be predicted from the observed current density, top height (or dominant and co-dominant height) and age (breast height age, stump age, or total age). Tables 1-3 and Table 16 can be used to make site index predictions and conversions. Figure 5 and Table 4 can be used to approximate initial density. The exact yield relationships at given values of current density, top height and age can be obtained using ExcelGYPSY.

Appendix 2. Metric Conversion Chart

1 cm	=	0.39370 in.
1 m	=	3.28083 ft.
1 m	=	1.09361 yards
1 ha	=	2.47105 acres
1 m^2	=	10.76385 ft^2
1 m^3	=	35.31435 ft^3
1 m^2/ha	=	4.3560 ft^2/acre
1 m^3/ha	=	14.2913 ft^3/acre
1 ha	=	10000 m^2
1 km	=	1000 m
1 km	=	0.62137 miles
1 km^2	=	100 ha
1 km^2	=	0.3861 $miles^2$
1 in.	=	2.5400 cm
1 ft.	=	0.3048 m
1 acre	=	0.4047 ha
1 ft^2	=	0.09290 m^2
1 ft^3	=	0.02832 m^3
1 ft^2/acre	=	0.2296 m^2/ha
1 ft^3/acre	=	0.06997 m^3/ha
1 mile	=	1.6093 km
1 $mile^2$	=	2.5898 km^2
1 $mile^2$	=	258.9846 ha
1 fbm	=	1 ft. × 1 ft. × 1 in.
1 fbm	=	0.0023597 m^3
1 Mfbm	=	1000 foot board measure (fbm)
1 Mfbm	=	2.3597 m^3
1 township	=	6 miles × 6 miles = 36 $mile^2$
1 township	=	9.6558 km × 9.6558 km = 93.2345 km^2
1 township	=	9323.45 ha
1 m^3 log	≈	233 board feet lumber (provincial average conversion factor)
1 Mfbm	≈	4.3 m^3 log (provincial average conversion factor)
